The primary function of the SIJ is to allow the transfer forces from the axial spine to the lower extremities providing the stability of the pelvic ring. In order to maintain the stability to facilitate its function, the joint is inherently immobile, allowing only minimal motion for dissipation of loads and facilitating parturition in females. Several studies have evaluated SI kinematics and essentially demonstrate limited but present motion in all three axes. Egund et al. looked at SI motion in asymptomatic volunteers in all planes and found that translation and rotation never exceeded 2 mm and 2°, respectively.¹² Vleeming et al. demonstrated similar findings, confirming that SIJ range of motion (ROM) rarely exceeded 2°. ^{13,14} The transfer of forces from the trunk to the ground is especially important with bipedal gait.¹⁵

A topic that is still unclear is the relationship between SIJ mobility and pain. Hypermobility has certainly been demonstrated as a cause of SIJ pain, particularly in patients with traumatic instability or multiparity.¹⁶ However, Stuesson et al. measured SIJ mobility in patients diagnosed with SIJ pain and found no significant differences

between symptomatic and asymptomatic patients, with maximal translation and rotation values of 1.6 mm and 3°, consistent with other kinematic studies.¹⁷ In summary, hypermobility can certainly be a source of SIJ pain; however, a painful joint is not necessarily, and perhaps rarely in the absence of trauma, hypermobile or unstable.

SACROILIAC JOINT DYSFUNCTION

Historically, SIJ dysfunction was at one point in the early 1900s thought by many surgeons to be the commonest cause of low back pain (LBP). When Mixter and Barr demonstrated radiating back and leg pain as a result of bulging and ruptured intervertebral discs in 1934 followed by the work of other authors including Ghormley lowering the rank of SIJ pathology in the differential diagnosis, the sacroiliac joint was nearly dismissed as a source of symptoms in LBP patients.^{18,19} Solenen et al. in 1957 re-explored this topic and identified a percentage of patients with pain originating from the SIJ while concluding that the SIJ was indeed a true articulation and a potential etiology of symptoms in patients presenting with LBP.²⁰

Several studies have demonstrated the presence of nerve fascicles containing myelinated and unmyelinated nerve fibers and various mechanoreceptors in the SIJ as well as in the respective periarticular tissues.^{21,22} The origin of these fibers is still subject to debate and may be variable among different patients as well as between different regions of the SIJ. Ultimately, most studies have demonstrated innervation from the lower lumbar and sacral nerve roots, predominantly from the dorsal rami of L4 through S1.^{23–25} Although the origin of the innervation has not been definitively shown, it is nonetheless clear that the SIJ and periarticular tissues are innervated and capable of producing pain in some proportion of patients.

Modern studies evaluating the prevalence of painful SIJ dysfunction are limited by the fact that there is no true single gold standard test to confirm the pain generator. Bernard and Kirkaldy-Willis examined the incidence of the SIJ as the etiology of symptoms in over 1,200 patients presenting with LBP and determined that the SIJ was responsible in 22.5% of patients, though these results were based almost solely on physical examination.²⁶ Other recent studies have acknowledged the limitations of physical exam and imaging alone, and utilized response to image-guided SIJ anesthetic injections as a confirmatory test. Schwarzer et al. evaluated 43 patients with LBP below

the lumbosacral junction and determined SIJ involvement by a combination of three factors: (1) response to intra-articular SIJ injection, (2) abnormalities on postarthrography CT scans and (3) concordant pain reproduction with distention testing. Seven patients in this study satisfied all three previously mentioned criteria, meaning that a conservative estimate of the prevalence of SIJ pain as the etiology of LBP symptoms would be 16%.¹ If significant relief with SIJ injection was used as the lone criteria, then prevalence of SIJ pain would be determined as 30% in this population. Although there is no true gold standard measure to confirm the SIJ as the etiology of symptoms, depending on inclusion criteria for LBP, the prevalence of SIJ etiology is approximately 15–20%.

PHYSICAL EXAMINATION AND DIAGNOSTIC TECHNIQUES

Evaluation of the SIJ should be part of a complete spine evaluation in all patients presenting with LBP as much to determine a diagnosis of SIJ pain as to evaluate differential diagnoses. The potential anatomic sources of pain and their relative prevalence in patients with axial back pain include the intervertebral discs (5–39%) and the zygapophyseal joints (15–40%), in addition to and less commonly the SIJs (6–16%).^{1,27,28} The physical examination of these patients is focused on delineating which of these structures is more likely to be the source of pain in a particular patient. Although pathology of each of these structures can result in LBP, their manifestations do have subtle differences that can aid the evaluating physician in forming an appropriate diagnostic algorithm and determining further workup.

Risk factors signifying altered SIJ loading or a history of trauma can identify the subset of patients complaining of LBP who might have pain from the SIJ. For example, activities that involve unilateral loading, i.e. kicking and throwing, place people at increased risk, as do altered spinal alignment and posture, for similar reasons.²⁹ Trauma, including physiologic hypermobility with pregnancy, has also been identified as a risk factor for the immediate or delayed presentation of SIJ pain.^{29–31}

The pattern of pain originating from the SIJ is somewhat different from discogenic or facetogenic lumbar spine pain. Typically, SI pain occurs below the waistline and is more commonly unilateral than bilateral (4:1) in nature.³² There are numerous provocative tests described in the literature, the most reliable and valid of which seem to be the

FABER, POSH, and Gaenslen's tests.³³ All of these tests are performed with the patient supine on the examination table. The FABER (Flexion, Abduction, External Rotation), or Patrick test, is performed by first flexing, abducting, and externally rotating the hip, and then moving it to an extended position. The POSH (Posterior Shear) test is performed by flexing the hip to 90°, adducting the hip slightly, and applying a posterior axial load to the femur. The Gaenslen's test is performed by maximally flexing one hip and concurrently maximally extending the contralateral hip. Pain in the posterior pelvic region over the SIJ in any of these three provocative tests may indicate an SIJ etiology.

Early studies looking at the validity of SIJ physical exam tests were disheartening, demonstrating poor validity and low reliability; however, these studies often evaluated one test in isolation and used a 90% threshold reduction in pain with injection as the comparative gold standard, which is somewhat limiting.³⁴ More recently, researchers have evaluated these tests in combination, and by comparing them to a more reasonable gold standard, pain relief threshold of 70% with injection, they have found more encouraging results. Reliability of the POSH, FABER, and Gaenslen's tests with the more reasonable injection relief threshold was higher than 80% and the POSH test in particular had the highest sensitivity and specificity.³⁴ Cibulka et al. evaluated the utility of these tests in combination and found that multiple provocative tests, as one would expect, improve utility with sensitivity, specificity, and positive predictive value all over 80%.³⁵

Intra-articular anesthetic SIJ injections are the closest thing to a gold standard similar to the case with discogenic and facetogenic back pain. Although there are few well controlled studies evaluating these tests, Rupert et al. recently performed a systematic review of the literature and reported level II evidence for the validity of SI diagnostic joint injections.³⁶ This was confirmed in more recent studies, which concluded these injections to be the most useful studies for SIJ dysfunction.³⁷ As is the case with other diagnostic injections, the patient reported quality and percentage pain relief following injections along with the duration of symptom relief implicates sacroiliac dysfunction for patients with suggestive symptoms.

IMAGING

Symptomatic sacroiliac dysfunction is not reliably demonstrated on any imaging study. Rather, the role of imaging

in the evaluation of patients with LBP and a possible sacroiliac etiology is to rule out other anatomic sources of back pain and more atypical etiologies of pain such as tumor, infection, and sacroiliitis. Plain radiography is often a first step in diagnostic imaging. The orientation, irregular surface, and complexity of the SIJs make the utility of plain films minimal in the absence of dramatic pathology. Ossification and degenerative changes can often be picked up on patients of increasing age, though there is no clear correlation between these findings and symptoms in the literature.³⁸

Computed tomography (CT) can better visualize degenerative bony changes, osteophytes and joint space narrowing, though again, there is no clear relationship to symptomatic SI dysfunction.³⁹ In the case of patients with acute or subacute symptoms along with history of trauma, CT can reveal more subtle fractures not demonstrated on plain films.

Functional imaging like bone scintigraphy or single-photon emission computed tomography (SPECT) can demonstrate inflammation in addition to other pathology and has been shown to have rather high specificity for SIJ disease.⁴⁰ Slipman et al., however, also demonstrated that the sensitivity of these studies is as low as 13%, making the utility of this type of imaging as a screening test for SIJ dysfunction quite minimal.

Magnetic resonance imaging is useful for both its functional imaging component, which can demonstrate inflammatory changes and stress fractures etc., and its ability to demonstrate fine anatomic detail. In patients with sacroiliitis from spondyloarthropathies, MRI is useful for detecting the subtle changes in the dorsal synovial aspect of the joint that represent earliest stages of SIJ involvement and occur prior to any radiographic changes.⁴¹ Similar to other advanced imaging techniques for this application, the concordance of MRI findings with symptomatic SI dysfunction has not been demonstrated and MRI is again most useful for ruling out other etiologies of LBP. Analogous to discogenic back pain, the diagnosis of SI dysfunction is difficult and relies on a combination of patient history, symptoms, and physical exam findings as a screening tool, while imaging serves more to detect and rule out other pathologies.

■ NONOPERATIVE MANAGEMENT

The management of SIJ pain is controversial and there are few high-quality studies comparing different modalities.

That said, SIJ pain management should take a two-pronged approach, with the goals of both providing symptomatic relief and addressing the underlying pathology. Several authors have discussed the nonoperative management of SIJ dysfunction in terms of acute phase (<3 days), recovery phase (3 days to 8 weeks), and maintenance phase (>8 weeks).⁴²

Patients in the acute phase of SI pain, like other acute musculoskeletal injuries, can benefit from relative rest, which is not equivalent to immobilization, as well as anti-inflammatory medications and cold therapy. In patients whom pain persists well into the recovery phase and beyond, other pathologies should be ruled out with physical exam and diagnostic studies as previously discussed. Further, these patients with persistent or recurrent symptoms should be evaluated specifically to rule out leg length discrepancy, spinal deformity, or gait abnormality, all of which can result in altered SI biomechanics and painful SIJ dysfunction and are amenable to specific therapies.

Physical therapy is aimed at the correction of asymmetries in stiffness and strength as well as exercise-induced lumbopelvic stabilization programs. Mooney et al. evaluated patients with SIJ dysfunction and found that they had EMG abnormalities in the pelvis stabilizing muscles that normalized with stabilization programs and were concordant with relief of their clinical symptoms.⁴³ SIJ stabilization can also be augmented with the aid of orthotics, such as SI belts, which were demonstrated to provide symptomatic relief specifically in patients with laxity resultant from multiple pregnancies.⁴³ Sasso et al. looked at 69 patients with symptomatic SI dysfunction and found that at 2 years, 95% had sustained good or excellent results with a structured physical therapy program alone.⁴⁴

Intra-articular steroid and local anesthetic injections have both a diagnostic and a therapeutic role for patients with symptomatic SIJ dysfunction and have been thoroughly investigated, with most studies demonstrating good to excellent pain relief lasting on average between 6 months and 1 year.^{45,46} The differential role between intra- and periarticular pathology has not been completely borne out in the literature, though Borowsky et al. did show improved pain relief in patients receiving intra- and periarticular combination injections relative to intra-articular injection alone.⁴⁷ These injections should be utilized sparingly, as with other intra-articular steroid injections, and as part of a combined approach incorporating physiotherapy, activity modification, and anti-inflammatory medications.

SIJ denervation procedures, most recently performed with radiofrequency ablation (RFA), have also received some attention in the literature and have been shown to have some limited success that is rather similar to that of intra-articular injections.⁴⁸ Perhaps secondary to the complex and redundant innervation of the SIJ, a number of patients have recurrence of symptoms between 6 and 12 months after denervation therapy. Nonetheless, these procedures merit further investigation and may become increasingly efficacious as we further elucidate SIJ innervation and refine RFA techniques.

■ OPERATIVE MANAGEMENT

Sacroiliac joint arthrodesis was utilized quite commonly in the early 1900s as a treatment for low back and buttock pain prior to Mixter and Barr's discovery of the herniated disc and the subsequent shift of focus to the disc as a primary etiology of back and leg pain. Sacroiliac joint arthrodesis is most commonly performed today for pelvic ring instability secondary to trauma and has been achieved through a number of techniques including uninstrumented bone grafting, anterior plating, and sacroiliac screws, in addition to other less frequently employed constructs. Studies evaluating outcomes after SI arthrodesis for isolated SI dysfunction are limited, as the vast majority of patients will respond to less invasive modalities such as physiotherapy and injections.

Waisbrod et al. performed 22 uninstrumented SIJ fusions for painful osteoarthritis and demonstrated a 70% rate of satisfactory results at follow-up between 12 and 55 months.⁴⁹ More recently, Buchowski et al. described a consecutive case series of 20 patients who underwent SIJ arthrodesis for symptomatic SI dysfunction diagnostically confirmed by good response to intra-articular injection.⁵⁰ Patients performed SF-36 forms preoperatively and postoperatively at final follow-up averaging 5.8 years. Patients demonstrated statistically significant improvement in nearly all categories including physical functioning and pain indices, and 85% of patients demonstrated solid fusion visible on plain radiographs. In recent years, the SIJ has gained increasing attention and minimally invasive fusion techniques for SI arthrodesis are being developed. Wise et al. performed SI arthrodesis in 13 patients using percutaneously placed fusion cages filled with bone morphogenetic protein-2 (BMP-2) and demonstrated a fusion rate of 89% with an average improvement of

4.9 points on the 10 point visual analog scale (VAS) at mean follow-up of 29 months.⁵¹

■ DISCUSSION

Sacroiliac joint dysfunction is an insufficiently understood clinical entity, owing both to the joint's highly specialized and unique anatomy and biomechanical properties and its complex innervations. The role of the SIJ in back pain has ranged the spectrum from primarily a focus on discogenic causes of LBP leading to little attention to the SIJ in the last 50 years as a cause of LBP to a more recent focus. Prevalence data, however, demonstrate that 15–20% of patients who present with LBP have symptoms originating from the SIJ. Given that abnormal lumbar spine MRI findings exist in a significant portion of asymptomatic patients, practitioners must be thoughtful about the potential for symptomatic SIJ dysfunction so as not to focus interventions on a potentially asymptomatic imaging finding elsewhere and ignore a painful SIJ.

The diagnosis of SI dysfunction in the context of LBP can be difficult, but SI pain has several qualities (below the belt line and often unilateral) that distinguish it from other common etiologies of LBP. Further, positive response to several provocative SIJ tests makes the positive predictive value for SIJ pain above 80%. If diagnosed appropriately, 95% of patients will improve with physical therapy and intra-articular SIJ injections. In the minority of patients with chronic debilitating SIJ pain that does not respond to nonoperative management, arthrodesis is an increasingly recognized potential treatment option. Novel techniques and instrumentation for minimally invasive and percutaneous SIJ fusion have yielded good early results with low complication rates and favorable outcomes. Clinicians, and spine surgeons especially, must shift some focus back to the SIJ in order to better care for the 15–20% of patients that walk into the office with LBP and have painful SIJ dysfunction.

INTRODUCTION

Dr Isadore M Tarlov was the first to recognize and describe perineurial cerebrospinal fluid (CSF) cysts. During his extensive cadaveric dissection of 30 terminal filum specimens at the Montreal Neurological Institute in 1938,¹ Dr Tarlov examined cysts that were found anatomically at the junction of extradural space and the posterior nerve of the respective dorsal root ganglion in 5 of the 30 cadavers. These perineurial cysts, localized specifically at the endoneurial-perineurial junction, were later named after Dr Tarlov to honor his extensive histopathological evaluation work.¹

Following Dr Tarlov's discovery, various authors attempted to further describe and characterize spinal cysts. In 1987, Goyal et al. clarified intraspinal cysts by classification into these five distinct categories: (1) perineurial cysts, also known as Tarlov's cysts or "nerve root diverticula,"² (2) nerve root sleeve dilations, (3) *intradural arachnoid cysts*, (4) *extradural arachnoid cysts*, and (5) *traumatic nerve root cysts*.

An even more simplified classification of spinal meningeal cysts was offered in 1988 by Nabors et al.:

- *Type I* (extradural meningeal cysts *without* spinal nerve root fibers)

- *Type II* (extradural meningeal cysts *with* spinal nerve root fibers)
- *Type III* (spinal *intradural* meningeal cysts).

Tarlov's cysts are Type II meningeal cysts, as classified by Dr Nabors. In fact, a Tarlov's cyst requires histopathological evidence of inclusion of spinal nerve root fibers to confirm its diagnosis.³

The prevalence of Tarlov's cysts is estimated at 1–4.6% in adult populations.⁴ Pertaining to gender, there does appear to be a slight predilection for the female population. Tarlov's cysts are more commonly seen in *young* adults. Specifically, 4% of patients with incidentally discovered lumbosacral lesions are less than 50 years of age whereas 1.3% of patients are >50 years of age.⁵ With improvements in and increased utilization of neuroimaging, the incidental finding of perineurial cysts continues to escalate.

PATHOPHYSIOLOGY

Tarlov's cysts are described as saccular, hollow lesions composed of nerve tissue containing CSF. From the time of Tarlov's original cadaveric studies, multiple hypotheses regarding pathogenesis have been offered.

Dr Tarlov's theory stemmed from his discovery that abundant inflammatory cells were embedded in the cyst

wall and adjacent tissues. As a result, Dr Tarlov felt that the pathogenesis of perineurial cysts was due to nerve root inflammation coupled with CSF inoculation. His second theory, developed following his work with the delayed oil-based contrast myelography studies, was that the inflammatory process may facilitate the sealing of meningeal diverticula, leading to the development of a symptomatic meningeal cyst. His ultimate theory was that trauma induces hemorrhage and leads to cystic degeneration and blood product deposition in the form of hemosiderin, which then leads to destroyed neural tissue or ischemic degeneration, and ultimately leads to breakage of venous drainage at the perineurium and epineurium and secondary infiltration of CSF.⁶⁻⁹

Additional theories proposed by Haddad, Strully and Heiser coincide with Tarlov's later theory. They hypothesized that dural lacerations following spinal surgery trigger pseudomeningocele formation. Park et al. argues that Tarlov's cysts have a significant genetic component and may develop secondary to congenital dural weakness or persistent embryonic fissures.^{5,10} Tarlov's cysts have also been associated with other congenital and connective tissue disorders as well as nerve root sheath duplications.⁷

In 1947, the Swedish anatomist, Bror Rexed, concurred with Tarlov's theory that cysts occur secondary to arachnoid mater overproliferation, followed by closure of the communication between the subarachnoid space and overproliferative arachnoid, ultimately leading to cyst formation.^{11,12} The most recognized pathophysiologic explanation includes perineurial cyst development secondary to microcommunication between the cyst cavity and subarachnoid space specifically at the endoneurial-perineurial junction of the nerve root dural sleeve. It is thought that pulsatile and *hydrodynamic* forces as well as compromised sheath integrity at this anatomical point may contribute to the development of a one-way ball-valve effect. Cerebrospinal fluid influx is permitted and CSF efflux is restricted, leading to gradual expansion of cyst size. As a result of the ball-valve phenomenon, we often see Tarlov's cysts located at the junction of the posterior nerve root and dorsal root ganglion.^{3,13} This theory of a one-way valve supports the observation that large Tarlov's cysts cause progressive neurological symptoms as they distort, compress or stretch the adjacent spinal nerve root. Less commonly, there is progression to erosion of adjacent sacral bone.¹⁴ In addition, this may lend itself to periosteal pain fiber irritation and subsequently insufficiency fractures.¹⁵

CLINICAL PRESENTATION

Tarlov's cysts as originally described by Dr Tarlov were asymptomatic; however, later in his studies he speculated that sacral radiculopathy may present as a common symptom. Dr Tarlov's initial paper was his most widely read and cited, and as a result, his initial impressions persisted for some time. Tarlov's cysts often present as small, multiple, and extending around the circumference of nerve roots within the sacral region especially at the sacral 2-3 nerve roots and therefore present with radiculopathy at the sacral 2-3 level.^{16,17} Nevertheless, Tarlov's cysts have been found to occur along any segment of the spinal cord.⁶

Large cysts and symptomatic cysts are quite rare. It is estimated that only 1% of Tarlov's cysts become large enough to cause symptoms related to local compression.^{4,5,18} However, it is thought that 17% may have an additive effect on other neuropathologies such as degenerative disc disease.¹⁸ Nonetheless, the natural history of these cysts is to enlarge, leading to progressive symptoms. The most common symptoms include sensory disturbances such as dysesthesias, lower back pain, sacral radiculopathy, and neurogenic claudication.¹⁹⁻²¹ Other common symptoms include bowel and bladder dysfunction, sexual dysfunction, and lower extremity motor weakness.^{8,22-24} Less commonly, a patient may present with intracranial hypotension if the cyst has ruptured, lending itself to positional headaches. There are numerous case reports of Tarlov's cysts presenting with common symptoms of physiologically distinct systems. One case report described a presacral cyst found via gynecological transvaginal ultrasound after the patient presented with pelvic pain.²⁵ Interestingly, Tarlov's cysts are often seen in the female population (for unknown reasons) and it is speculated that there may be a reluctance among female patients to fully disclose the entirety of pelvic symptoms to spine specialists (mostly men), and this may have perception of the medical significance of Tarlov's cysts throughout history.²⁶ One might elicit a history of exacerbation of pain with coughing, standing, and changing of position. These symptoms serve to prove the aforementioned pathologic theory of the ball-valve phenomenon, wherein an increase in CSF pressure induces a mechanic pressure to spinal nerve roots and activates neurogenic symptoms. Alleviation of symptoms is present in the recumbent position. Lastly, very rarely, thoracic Tarlov's cysts have been described to elicit angina-like symptoms.²⁷

DIAGNOSIS

Tarlov's cysts are often detected incidentally during spinal computed tomography (CT) or magnetic resonance imaging (MRI). Langdown and colleagues reported that 70% of Tarlov's cysts detected by MRI were found to be asymptomatic, whereas only 13% were found to be symptomatic. With the increased usage and reliance on MRI for symptoms such as lower back pain, spinal radiculopathy, and lower extremity weakness, the incidence of incidental meningeal cyst diagnosis is on the rise; other common incidental findings during lumbosacral imaging include vertebral hemangiomas, fibrolipomas, synovial cysts, and sacral meningoceles.²⁸ MRI, the imaging modality of choice for diagnostic purposes, also aids in surgical planning through its high enhanced resolution of tissue density, multiplanar capabilities, and characterization of the cyst and surrounding structures. Tarlov's cysts appear as round, well-circumscribed masses. T1-weighted images reveal low signal while T1-weighted images reveal high signal, coinciding with radiographic characteristics of CSF.^{4,29,30} The cysts often extend to envelope nerve roots and may reveal impinge on neighboring nerve roots.³¹

Computed tomography (CT) is helpful for visualization of the vertebral body and posterior elements that will show scalloping, rounded paravertebral shadow or insufficiency fractures. The cyst appears isodense with CSF on noncontrast CT studies. CT may also be used for image guidance during percutaneous aspiration.⁴ Plain radiographs are often negative for pathology; however, in the late stages, severe bony erosion of the vertebral body or neural foramina may be visualized.

Myelography is often utilized in diagnosis, especially when MRI is contraindicated. More importantly, myelography with delayed CT has greatly advanced our understanding of the pathophysiology of Tarlov's cysts.

Although a slightly more invasive imaging modality, direct visualization of filling patterns can lead to diagnosis.³³ Shrieber and Haddad were one of the first to describe the characteristic delayed filling pattern using oil-based pantopaque contrast-enhanced myelography. Here, the oil-based contrast was not immediately visualized but was seen hours, days or even weeks later.³³ Later utilized by Dr. Tarlov with works published in 1970, he was able to determine the difference between meningeal diverticula and Tarlov's cysts.

Computed tomography conducted 30–60 minutes after intrathecal contrast administration can reveal delayed filling of meningeal cysts. From this imaging, one can conclude that there is a microcommunication between the cyst cavity and the subarachnoid space, lending itself to a very slow hydrodynamic process coinciding with the valved phenomenon. Other authors adopt the CSF transudation theory, which proposes that CSF migrates across the cyst wall membrane into the perineurial cyst cavity. Additional claims include a lack of true communication with the spinal subarachnoid space and that detection of myelographic defects is extra-arachnoid in nature.^{2,6,34} This is contrary to meningeal diverticula, which are in free communication with the subarachnoid space and rapid fill during myelography.²² This is an important diagnostic pearl as meningeal diverticula are less likely to produce symptoms. In addition, meningeal diverticula often appear proximal to the dorsal root ganglion at multiple thoracic levels. Tarlov's cysts may appear in multiple locations throughout the lumbosacral spine but usually appear extradural and directly at or immediately distal to the junction of the posterior nerve root and dorsal root ganglion.^{8,22} (Table 89.1 from Acosta et al. regarding Tarlov's classification of spinal cysts).

Although imaging can suggest the diagnosis of a meningeal cyst through radiographic features, Tarlov's

Table 89.1: Tarlov's classification of spinal cysts.*

<i>Lesion</i>	<i>Communication W/SS</i>	<i>Filling pattern on myelography</i>	<i>Location along nerve root</i>	<i>Nerve fibers W/in cyst</i>
Perineurial cysts (Tarlov cysts)	No	Delayed filling	At or distal to junction of pst nerve root and DRG	Yes
Meningeal diverticula	Yes	Rapid filling	Proximal to DRG	No
Long arachnoidal prolongations	Yes	Rapid filling	Continuous prolongation of SS over nerve root	NA [†]

*NA: Not applicable; pst: Posterior; SS: Subarachnoid space.

[†]Although these can be confused with meningeal diverticula and perineurial cysts, arachnoidal prolongations are not actual cystic lesions.

cysts require a histopathologic diagnosis to show the presence of nerve fibers, ganglionic cells, and possibly old microhemorrhages in the form of hemosiderin.⁷ One must visualize neural fiber involvement. The meningeal cyst walls are composed of perineurium. In a histopathologic study, the outer cyst wall is formed of vascularized connective tissue whereas the inner cyst wall contains flattened membranous arachnoid tissue. Peripheral nerve fibers and ganglionic cells can be found embedded into the cyst wall.⁸ Nerve roots are found within the cyst wall in about 75% of all Tarlov's cysts.⁷ In addition, nerve roots are also seen to lie within the actual cyst cavity.

Rarely performed adjunct studies include electromyography and nerve conduction studies, which may exhibit decreased sural nerve action potentials and sensory nerve conduction velocity loss.³⁵ Motor nerve conduction studies are often normal, which coincides with the location of most Tarlov's cysts adjacent to the dorsal root ganglion. Urodynamic studies can evaluate for bladder dysfunction.

TREATMENT OPTIONS

There is no gold standard or clearly defined criteria for surgical or conservative management of Tarlov's cysts. There are no published data with regard to the natural history of Tarlov's cysts. As a result, clinical judgment is of the utmost importance in determining the etiology of the patient's symptoms and whether the meningeal cyst is a likely cause. General consensus remains that if the patient is symptomatic, treatment is recommended. This consensus is challenged when a second pathology is present, such as disc protrusion or neuroforaminal stenosis. At this point, the clinician must determine which pathology is most likely the cause. Once the decision is made to treat, typical conservative spinal management is recommended in the form of analgesics such as nonsteroidal anti-inflammatory medications and the tricyclics, especially nortriptyline and desipramine, as these have the highest therapeutic index and are inexpensive.²⁶ Second-line medications include gabapentin and opioids. In addition, conservative measures include physical therapy, oral steroids, and finally, epidural steroid injections. Langdown's case series of Tarlov's cysts treated conservatively exhibited a 3.3 median year follow-up radiograph showing no changes to the cyst features.¹⁸ After a significant period of failed therapy, more invasive measures are suggested.

There is a myriad of proposed surgical strategies. Surgical approaches can be organized into two major subtypes: CSF flow diversion and surgical decompression.

CEREBROSPINAL FLOW DIVERSION

Options include: external CSF drainage,³⁶ percutaneous cyst drainage,^{4,37} percutaneous fibrin glue injection,^{38,39} insertion of a cyst-subarachnoid shunt,⁴⁰ cyst-peritoneal shunt,³⁹ or lumboperitoneal shunt.⁴⁰ CT-guided percutaneous aspiration of cyst fluid is fraught with all the pitfalls of cyst aspiration in other parts of the body. The fluid always reaccumulates as long as the cyst wall remains intact, and therefore symptoms often recur. There are multiple published series of Tarlov's cysts treated with percutaneous cyst aspiration followed by percutaneous fibrin glue administration. Original studies showed improvement in symptoms after the first 6 months. However, 75% of the cases developed postprocedural aseptic meningitis.³⁸ Repeat studies showed 80% improvement in symptoms after 23 months; however, there were still two cases of transitory postprocedural aseptic meningitis.²³ The largest retrospective study of 122 patients conducted by Murphy et al. showed symptomatic improvement in 65% of the patients, with 23% symptomatic recurrence rate after only 7 months.³⁰ As a result, the general consensus among authors is that percutaneous cyst aspiration, with or without fibrin glue injection, has clinical utility.

Given the pathophysiology one-way pressure valve theory, one treatment measure aims at decreasing the pulsatile pressure cephalad to the cyst valve, thereby decreasing the size of the cyst, thereby relieving impingement of the nerve root. This is done via lumboperitoneal shunting. Vartels and associates reported that two patients with leg and back pain who were treated with lumboperitoneal shunt found symptomatic relief after a median of 10 months. Often this procedure is suggested for patients with multiple cysts, where the cause of the symptomatology is difficult to determine. Nevertheless, as with all shunts, there is an added risk of malfunction and infection. Cysto-subarachnoid shunts are used primarily as an adjunct to microsurgical decompression to equalize pressures without requiring cyst wall resection and encountering complications of neurological sequelae from neural fiber resection. The CSF flow diversion techniques may also serve as a more minimally invasive diagnostic measure when there is a question about the clinical significance of the cyst. Nevertheless, many argue that the best long-term results are yielded with a more aggressive surgical approach.²²

SURGICAL DECOMPRESSION

Tarlov originally advocated for complete cyst removal with excision of complete posterior nerve root and ganglion.

This was utilized for many years following Tarlov's original work; however, resulting morbidity including significant neurological deficits led many to seek other options. Simple posterior sacral bony decompression via laminectomy was proposed and yields mild morbidity but has low success rate as well as complications such as durotomy or neurotomy. Microsurgical excision involves laminectomy with microsurgical cyst wall manipulation. Various procedures include: imbrication (which involves suturing of the cyst wall),⁴¹ cyst neck ligation (which closes communication between the cyst cavity and intrathecal sac), cyst fenestration (which also opens the communication between intrathecal sac and cyst cavity), and lastly cyst wall resection (which often involves sacrificing the nerve root). There have been published reports that show very low morbidity with laminectomy and,^{7,42} cyst neck ligation,^{42,43} cyst wall resection,^{7,9,31} and cyst imbrications, cyst fenestrations and bipolar cautery to shrink the size of the cyst.^{2,3,43,44} Meticulous surgical planning is of utmost importance. Often, a simple laminectomy via standard posterior approach with careful en masse excision of the cyst wall is the option of choice. Neural elements are often involved and the neural sheath must be excised.

PATIENT SELECTION

The clinical indication for surgery has been studied by a very few. Voyadzis and associates presented cyst diameter criteria for surgical treatment. Cysts greater in diameter than 1.5 cm, with associated radicular or bowel/bladder dysfunction, tended to improve at a better rate.^{7,45} Multiple cysts, as well as mega cysts, (> 1.5 cm) were associated with significant greater morbidity. Neulen et al. showed that patients with single or multiple perineural cysts > 1 cm in diameter with delayed filling seen on postmyelographic CT scan were likely to benefit from surgical intervention. Pain associated with Valsalva and postural maneuvers was shown to likely benefit from surgical decompression.⁹

Kunz and associates evaluated surgical treatment of Tarlov's cysts and compared it to conservative treatment. In a study of 16 patients, they ascertained that there is no clinically significant difference in symptomatic improvement between conservative and surgical treatment because of the associated postsurgical pain. As a result, surgical intervention should be recommended only for a patient with a significant neurological deficit as well as a short history exacerbated by postural changes.

PREOPERATIVE WORK-UP

Magnetic resonance imaging of the lumbosacral spine should be obtained for every patient. In addition, myelography with delayed CT is useful in distinguishing between meningeal diverticula. A CT scan will help disclose any bony erosions and instability that may require operative stabilization.

TECHNIQUE

Careful dissection using nerve root retraction and penfield is pertinent. Often, neural elements are involved within the cyst. One should take great care to maintain nerve root and nerve sheath without excision. However, such as in the case of Sen et al., this does not always correspond to residual neurological deficits. With large cysts, ligation of the neck precedes en masse excision.⁴⁶

Often, an intraoperative Valsalva maneuver is utilized to exhibit CSF flow through the posterior nerve root sheath into the cyst.²⁵ In addition, surgical cyst fenestration and imbrications with the use of electrophysiological monitoring and the use of fat or muscle grafting to reinforce closure^{9,22} are proposed.

The specimen should be sent to pathology to evaluate for inclusion of neural elements confirming the diagnosis of Tarlov's cyst.

POSITIONING AND ROOM SETUP

The patient should be positioned prone in natural alignment on a standard operating room table with a supporting frame, such as the Wilson™ Frame by Mizuho to maintain the patient in a flexed position. A midline incision over the sacral prominence along the lines of Langerhan is created with the guidance of multiplanar fluoroscopy. The incision length should extend from L5 to S3 approximately 5 cm in length incision, depending upon the size and location of the cyst. Using an 11'-blade needle, the skin and subcutaneous should be sharply incised in the midline with careful dissection through the paravertebral musculature to the subperiosteum of the sacral spinous tubercles. At this point, the sacral roof will be encountered. The blue-hued cyst may be visualized beneath the sacral lamina, especially when there is significant bony erosion and the bone is thinned. Monopolar cautery may easily fracture the thinned bone and should be utilized with caution. Preoperative planning for the bony window should be created through visualizing cyst boundaries on high-resolution thin-cut CT with the ultimate goal of exposure of sufficient cyst.⁴⁷ When the cyst is large enough, it is not necessary to fully expose the

range of cyst. Pertinently, adequate exposure includes visualization of the cephalad–thecal sac.⁸ A high-speed drill is used to create bilateral sacral troughs, which are then connected through horizontal linear cuts of the sacral roof. These cuts should lay rostral and caudad to the cyst. The sacral window is then elevated as one piece with careful preservation of the integrity of the cyst wall roof. The bone should be saved for closing and plating.

The microscope should be positioned at this point. Microsurgical decompression aims to serve three important purposes: (1) decompress yet preserve surrounding nerve roots, (2) halt bony erosion, and (3) obliterate any persistent connection between the lumbosacral cistern and the cyst cavity. As previously stated, electrophysiologic monitoring is helpful during dissection of the cyst wall from the sacral nerve roots, which tend to travel adjacent to or through the cyst. Prior to cyst fenestration, the cyst should be thoroughly evaluated for the presence of adjacent nerve roots. Once a safe region for transection is identified, the microscissors are used to open the cyst and aspirate the contents. This will result in the cyst's collapse. Imbrication of the cyst's wall can be utilized if the remaining nerve root sheaths are not too fragile or attenuated. Attention should be now directed toward dissection with identification of any microcommunications with the subarachnoid space. The complete cyst wall should be resected and the dural sac should be respected. The cyst wall should be sent for pathologic evaluation of included neural elements.

Closure often requires local fat or muscle grafting, which is placed at the located communication to prevent future CSF leak. At this point, the anesthesiologist should be asked to stimulate Valsava pressure to ensure proper placement of the graft. Local muscle grafts are preferred because of their durability and longevity, as fat grafts tend to diminish with time. Enough cyst wall edge should remain to approximate the cyst wall edges superficial to adjacent graft placement. This should be performed with no absorbable suture in an interrupted fashion for tensile strength and permanence. Fervid cyst wall resection can lend itself to large defects, which may prove difficult to close. The layered closure may then include fibrin glue and/or dural graft matrix. The bone graft should then be repositioned en bloc and secured to the sacral lamina with titanium plates and screws. Some authors suggest placement of a subarachnoid lumbar drain for 7 days to prevent CSF leak; however, there is no current study to date to validate its use.^{9,43}

RISKS OF PROCEDURES

Complications after excision include infection, CSF leak, and neurological deficit. Surgical adjuncts include fibrin glue and absorbable gelatin sponge placement; muscle and fat grafting is used to fill the cyst or cover any dural defects. Nevertheless, there have been reports of neurological worsening and even more devastating sequelae such as cauda equina syndrome following translocation of grafts. Cerebrospinal fluid leakage is quoted as the most common complication and reported by Neulen et al. as present in 1 in every 13 patients, by Guo et al. as 1 in every 11 patients and as common as 1 in every 3 patients by Langdown et al.^{8,13,18}

COMPLICATION AVOIDANCE

Complication avoidance starts with patient selection. Patients with radicular symptoms, exacerbated with positional changes and Valsalva maneuvers or patients with bowel/bladdery dysfunction, benefit most from surgery. Electing proper surgical management in the form of complete cyst resection, if possible with minimal usage of surgical adjuncts, will decrease the likelihood of complications. Often, lumbar drainage is utilized for 3–7 days postoperatively to prevent CSF leakage. The use of intraoperative neuromonitoring, in the form of somatosensory evoked potentials, may minimize serious injury to sacral nerve roots during microsurgical excision.⁹ Close postoperative assessment is imperative when muscle flaps and fat grafts are utilized to quickly evaluate for translocation.

PROGNOSIS

The cyst recurrence rate is fairly low and ranges from 0% to 10%.^{8,13,43,48} Symptomatic improvement following microsurgical treatment varies from 38% to 100%. Interestingly, it appears as if most symptoms improve in >90% of cases.

However, radicular symptoms may not benefit from surgery as they are occasionally an indicator of permanent spinal nerve impingement and this may lend to chronic pain syndromes.

OUTCOMES OF TARLOV'S CYST SPINE SURGERY PROCEDURES

It is evident from the author's extensive literature review that surgical correction in the form of laminectomy, cyst

resection and duraplasty lends itself to complete or substantial resolution of the preoperative symptoms. Very rarely does the patient experience temporary or permanent worsening of his or her preoperative symptoms. Although the options for surgical cyst management are varied, often the proposed surgical management carries a low risk of postoperative neurological deficits. It appears that fibrin glue injections are more commonly associated with a smaller percentage of improvements. Cerebrospinal fluid leaks tend to be the most common complication of surgical repair. It should be noted that laminoplasty and replacement of the bony graft appear to support dural closure and decrease the chance of a CSF leak. Furthermore, this reconstitution of bone provides additional stability, eventually preventing future sacral insufficiency fractures.⁴⁹

CONCLUSION

Spinal meningeal cysts, more commonly known as Tarlov's cysts, are a documented cause of sacral radiculopathy and pain. They are common in the general population and best visualized with MRI and CT myelography. Usually asymptomatic, their symptoms can include sacral radiculopathy, dysesthesias and a myriad of unexpected symptoms, and therefore should be considered as part of a differential diagnosis of neurological symptoms in the setting of minimal degenerative disease. Tarlov's cysts are believed to be caused by congenital weakness, trauma or inflammation of the dura matched with disturbance of CSF hydrodynamics.

Historically treated with various techniques, laminectomy, cyst resection and duraplasty are the preferred treatments. Judicious use of myocutaneous flaps and fibrin glue is recommended. When preoperative planning with consideration of electrophysiological and lumbar drain placement is utilized, outcomes have proven favorable, with serious complications occurring at a very low rate. Patient symptoms of motor deficits and sacral pain show the most improvement with sensory deficit improvement occurring at a less common rate.

- » Patient Evaluation with Failed Back Syndrome
- » Treatment Options

INTRODUCTION

Failed back syndrome (FBS), also known as failed back surgery syndrome (FBSS), is defined as persistent or recurrent chronic disabling lower back pain after surgery on the lumbosacral spine with or without sciatic symptoms.¹⁻⁴ The incidence of FBS ranges from 10% to 40% of all patients undergoing lumbar spine surgery, including discectomies, laminectomies, and posterior spinal fusions.¹ In addition, multiple nonoperative modalities are used, resulting in an overall higher rate of treatment costs.^{1,5} Success rates of subsequent surgeries are significantly less than the index surgery.^{6,7} Patients who undergo multiple lumbar spine surgeries tend to have greater leg pain, greater disability based on Oswestry disability score, higher unemployment, and lower health-related quality of life based on SF-36 and EQ-5D compared to other chronic conditions.^{1,5}

CAUSES

Failed back syndrome may arise as a result of several types of causes, including (1) patient factors, such as psychological illness, comorbidities, compensation or personal gain; (2) differential pathology, such as vascular claudication, osteoarthritis, or diabetic neuropathy; (3) surgical factors, including improper technique, incorrect surgery, wrong surgical level, or poor patient selection; (4) immediate postoperative complications, such as dural and nerve root injuries, infection, pseudomeningocele, or arachnoiditis;

and (5) long-term postoperative complications, including epidural fibrosis, pseudoarthrosis, and progressive disease. Failed back syndrome in most patients can be traced to multiple factors. However, each of these causes is discussed separately in this chapter and must be treated distinctly.^{1,7,8}

Patient Factors

Patient factors play a significant role in postoperative outcome. Preoperative psychological testing for significant factors is recommended to improve the success of a patient's outcome.

Psychosocial factors that increase the risk of lower function and dissatisfaction postoperatively include a history of psychiatric illness, including depression, anxiety, poor coping mechanisms, somatization and hypochondriasis; drug abuse and alcoholism; and limited social support or marital discord. Spine pathology can worsen these pre-existing conditions. In addition, personal injury claim, secondary gain or worker compensation claims all decrease the likelihood of a good or excellent postoperative outcome.⁹⁻¹² Patients with leg pain for >2 years, preoperative resting numbness and footdrop, decreased preoperative function, and regular preoperative use of analgesics demonstrated lower function and dissatisfaction postoperatively.^{13,14}

However, pretreatment physical findings, presurgical pain intensity, and activity influence have not been shown to affect outcomes.¹¹ In addition, when a surgically

treatable pathology exists, the likelihood of a satisfactory postoperative outcome is higher. Return to work status is also correlated with a patient's preoperative work status. Patients who are on long-term sick leave or receiving disability benefits are less likely to return to work. Consulting with an occupational physician can help return the patient to the workforce, and it is important to keep the patient in the workforce preoperatively. It is also important to give patients realistic expectations on their respective potential outcomes and to inform them that fewer will have complete pain relief or return to their pain level or function prior to the onset of their symptoms.¹⁵

Lumbar Preoperative Pathology

The differential diagnosis of lower extremity pain includes hip pathology (i.e. osteoarthritis, avascular necrosis and labral tears) and peripheral vascular disease. Patients with failed back syndrome also have a higher incidence of associated nerve entrapment syndromes, most specifically piriformis syndrome, that often present with symptoms similar to a disc herniation throughout their lower extremities.^{1,7,16} Patients with a primary source of pain other than the spine can demonstrate abnormal magnetic resonance imaging (MRI) findings. Up to 64% of asymptomatic patients have evidence of abnormal intervertebral discs and disc herniations, as well as findings of facet arthropathy, spondylolysis and spondylolisthesis, and central stenosis.^{17,18}

Elderly patients with arthritic spine conditions frequently have concomitant hip pathology.¹⁶ In patients with low back pain who presented at a spine clinic, almost 20% had a combination of spine with hip and sacroiliac (SI) pain, and almost 8% had only hip or SI joint pathology.¹⁹ Up to 10% had no abnormalities in the spine, hip, or SI joint. Another study demonstrated a prevalence of up to 32% of hip pathology, including osteoarthritis and avascular necrosis.²⁰ More specifically, disc degeneration of the upper lumbar intervertebral discs demonstrates an association with hip pain, and therefore it is important to differentiate the main cause of pain as changes may be present in both the hip and the spine.²¹ There is a significant association with degenerative disc disease in the lumbar spine and in the hip, although lumbar degeneration has been shown to precede osteoarthritis of the hip.²²

History and physical examination as well as radiographs and diagnostic testing are useful in localizing the

primary source of pain. Signs and symptoms of hip pathology include groin pain, buttock pain, decreased hip range of motion, and lateral thigh pain. Specifically, tenderness to palpation are signs of bursitis of the greater trochanteric, ischium, and iliopsoas. Greater trochanteric bursitis has tenderness to palpation at the lateral aspect of the hip over the greater trochanter. Ischial bursitis has tenderness to palpation directly over the ischial tuberosity and results in pain with sitting and resisted hip flexion. Iliopsoas bursitis is located in the anterior hip with tenderness to palpation below the inguinal ligament and pain with hip extension.^{23,24} Pain localized to the groin or buttock region is more common with isolated hip pathology. In addition, worsening pain with weight bearing, pain and decreased internal and external rotation of the hip can be detected by physical examination. Weight-bearing radiographs of the hips demonstrate decreased joint space, osteophyte formation, and subchondral sclerosis and cyst formation.^{16,25,26} An MRI arthrogram and intra-articular hip injections of steroids with symptomatic relief are highly sensitive and specific for hip pathology and should prompt a referral to a hip specialist.¹⁶

Piriformis syndrome is caused by piriformis pathology resulting in compression and neuritis of the sciatic nerve resulting in symptoms similar to lumbar radiculopathy with pain radiating down the posterior thigh and leg.²⁷⁻³² However, symptoms are usually specific to muscles distal to the piriformis innervated by the sciatic nerve.³⁰ Symptoms include hip and buttock pain, greater sciatic notch tenderness, worsening of symptoms with sitting for >20 minutes, and with activities that result in piriformis stretching such as cross-legged sitting or internal rotation of the leg during ambulation.³⁰ Over 80% of patients with piriformis syndrome present with radiculopathy and symptoms radiating down the leg.^{27,29} No significant association is noted between piriformis syndrome and lumbar pathology.²⁷⁻²⁹

Traditionally, physical examination findings of piriformis syndrome that recreate the patient's radicular symptoms including the Freiberg maneuver (passive internal rotation of the hip), Pace maneuver (resisted hip abduction and external rotation), the piriformis test (with the patient on their side, the hip is flexed to 60° and downward pressure is placed on the knee), and Beatty's maneuver (with the patient on their side, the patient holds their flexed knee off the table).²⁸⁻³⁰ Recently, the FAIR test (a combination of flexion, adduction, and internal

rotation of the hip) in combination with direct palpation over the piriformis muscle resulting in reproduction of the patient's symptoms has been shown to be highly diagnostic of piriformis syndrome.²⁷ Electromyography (EMG) findings will demonstrate no abnormalities in muscles proximal to the piriformis muscles, with various abnormalities in muscles distal to it. Electromyography can be combined with active maneuvers, including the FAIR test, to increase the reliability of the diagnosis of piriformis syndrome.^{30,33} Injection of anesthetic and steroid into the piriformis tendon has also been shown to be both diagnostic and therapeutic for piriformis syndrome. Treatment begins with extensive use of anti-inflammatory medication and physical therapy and rarely surgical intervention, involving the release of the piriformis insertion with the release of the sciatic nerve.²⁷⁻³¹

Intermittent claudication can be due to both vascular and neurogenic causes, both of which can present with similar symptoms and are frequently both present in patients.³⁴ Although it causes symptoms similar to lumbar spinal stenosis, peripheral vascular disease requires a completely different diagnostic and treatment approach.¹⁶ History and physical examination are paramount in discerning between neurogenic and vascular claudication as the primary cause of a patient's symptoms.³⁵ Abnormal low-extremity pulses usually spark the suspicion for a vascular etiology. However, the sensitivity of this is only 60%.³⁶ Other signs and symptoms include skin discoloration, ulcers, and hair loss in the lower extremities.¹⁶ Both neurogenic and vascular claudication frequently present with atypical signs and symptoms. Therefore, ancillary tests, including EMG or ABI, are important tools in

distinguishing the two when the history and physical examination are unequivocal.^{35,37} An ABI of <0.90 has a sensitivity and specificity of 85%, and the gold standard for diagnosis is a computed tomographic (CT) angiography.³⁷ Any of these findings should prompt a referral to a vascular surgeon for further evaluation and treatment.

Surgical Factors

Surgical factors can also be a cause of FBS. Surgical factors include inadequate decompression of the lateral recess and foramen, joint instability from excessive decompression, poor postoperative alignment, incorrect level and poor patient selection.³⁸⁻⁴¹

For patients who present with signs and symptoms of spinal stenosis, all areas of pathology should be identified, including central canal stenosis, lateral recess stenosis, and foraminal stenosis, and they should be thoroughly decompressed.⁴¹ Lateral recess stenosis and foraminal stenosis are the areas with the highest likelihood of residual stenosis causing continued postoperative pain.^{1,41} Those patients with identifiable continued stenosis have a higher probability of a successful second decompressive surgery.^{1,41} However, excessive decompression with excessive bone removal from the facet joint or the pars interarticularis can lead to instability and continued pain if no arthrodesis is performed (Figs. 90.1A and B). It is important to leave the pars interarticularis intact to not destabilize the spinal segment.⁴²

Both preoperative and postoperative sagittal alignment has been shown to correlate with postoperative surgical

Figs. 90.1A and B: (A) Postoperative instability following excessive decompression; and (B) Postoperative AP and lateral radiographs after anterior lumbar interbody fusion from L3-L5 and posterior spinal fusion with instrumentation from L3-L5.

success as well as degeneration of adjacent segments. Patients with decreased preoperative lumbar lordosis demonstrated significantly poorer results following laminectomy.⁴³ Patients with a postoperative normal C7 plumb line and normal sacral inclination demonstrated the lowest level of adjacent segment degenerative changes with a significant decrease in retrolisthesis of adjacent segments.²⁵ Postoperative flatback syndrome (Figs. 90.2A and B), also known as fixed sagittal balance and loss of lumbar lordosis, was originally described by Moe and Denis.⁴⁴ It was classically caused by Harrington distraction instrumentation into the lower lumbar spine due to distractive forces and a straight rod along the posterior elements of the spine.⁴⁵⁻⁴⁷ More commonly, it can result from failure to recreate lordosis during arthrodesis, development of pseudarthrosis or loss of correction, kyphosis at the TL junction, degeneration or decompression in adjacent segments, and hip flexion contractures.⁴⁷ Flatback syndrome results in compensation with hyperextension of other spinal segments, and flexion of the hips and knees to recreate horizontal gaze as well as spasm and atrophy of lower back muscles.^{40,47} In the long term, a flatback results in increased degeneration of adjacent segments and worse clinical outcomes.⁴⁸ Pseudarthrosis can be due to large forces applied to distal instrumentation with further caudal arthrodesis, with a greater increase when distal regional lordosis is not recreated during surgery. Proximally, thoracolumbar junctional kyphosis may also be due to failure to contour the rod.⁴⁷

Figs. 90.2A and B: (A) AP and lateral radiographs of postoperative flatback syndrome following posterior fusion with loss of lordosis and loss of sagittal balance; and (B) AP and lateral radiographs of following surgical correction of the flatback deformity with significant improvement in sagittal balance.

Identifying the surgical level is also paramount for success. Wrong-level surgery is unfortunately not uncommon in spine surgery. If the patient's offending pathology is not treated, surgery cannot be expected to result in significant relief of symptoms.¹ In patients with postoperative symptoms similar to their preoperative symptoms, inadequate treatment of the offending pathology should be ruled out as the source of the pain.

Patients with preoperative profound or progressive neurologic deficits are the best candidates for surgical intervention.⁴¹ However, most patients with chronic back and leg pain and nondiscrete neurologic deficits should be trialed with an extensive nonoperative course prior to surgical intervention as they have a lower likelihood of surgical success.⁴¹

Immediate Postoperative Complications

Immediate intraoperative and postoperative complications can increase the incidence of continued pain following surgery. These include nerve root and dural injuries, infection, pseudomeningocele, arachnoiditis, and paraspinal muscle injury.^{1,2,49} Damage to nerve roots both preoperatively and intraoperatively can lead to continued symptoms even following sufficient decompression.⁵⁰ Chronic compression by osteophytes and intervertebral disc material of nerve roots and of epidural veins, dilation of other epidural veins resulting in nerve root hypoxia, and perineural fibrosis can all lead to chronic nerve root damage.⁵⁰ Inadequate exposure intraoperatively can result in excessive nerve root retraction, resulting in further injury to nerve roots with chronic damage in addition to the changes already present.¹

Incidental durotomies have an incidence of 2–17% of spine surgeries, with a higher incidence in surgery in the thoracolumbar region, in women compared to men, with degenerative spondylolisthesis and juxtafacet cysts, and most significantly in revision surgery.⁵¹⁻⁵⁴ Immediate repair, with additional reinforcement using a collagen patch and fibrin glue with or without a nonaspirating drain, is the preferred treatment.⁵⁵ A Valsalva maneuver can be used to test the repair. The patient is also restricted to the supine position for 48 hours postoperatively and can ambulate per protocol as the patient's symptoms allow.⁵⁵ Failure rates for dural repair are <10%, with a significantly higher rate in revision surgery, up to 13%.⁵² A study evaluating 2-year outcomes following incidental durotomies demonstrated no difference in postoperative outcome. There was

no difference in long-term postoperative rates of infection, need for reoperation, neurologic injury, back or leg pain according to the visual analog scale, and no difference in functional disability based on the Oswestry Disability Index.⁵⁴

Postoperative infection is a devastating complication following surgery, usually requiring multiple repeat irrigation and debridement. The most common organism for postoperative spinal infection is *Staphylococcus aureus*.^{56,57} Risk factors for postoperative infections include older age, diabetes, elevated body mass index, American Society of Anesthesiologists (ASA) classification >2, serum albumin <3.5 g/dL indicating a diminished nutritional status, resident involvement, and procedures >300 minutes.⁵⁸⁻⁶⁰ The most significant MRI findings indicative of an infection included bony involvement and destructive characteristics.⁶¹ Treatment of a postoperative spinal wound infection requires aggressive irrigation and debridement and antibiotic therapy.^{56,59,62} If hardware is present, it is retained to maintain stability to the spine.^{56,59,62} Occasionally, repeat debridements are required, but primary closure is almost always possible.^{56,59,62} Patients infected with a history of diabetes mellitus (DM), methicillin-resistant *Staphylococcus aureus* (MRSA), bacteremia, presence of instrumentation, and allograft bone graft in the lumbar spine usually require multiple irrigation and debridements.⁶³ Patients with infections that are treated demonstrate significant improvement in disability outcomes and back and leg pain 2 years following their index procedure and with resolution of their infection.⁶⁴ However, disability outcomes, back and leg pain were all significantly worse than those patients without an infection.⁶⁴ Approximately 10% of patients in one study demonstrated pseudarthrosis in long-term follow-up.⁵⁶ In addition, a significant number of patients did not achieve a clinically significant improvement in their disability score.⁶⁴ Although patients did demonstrate improvement, patients with infections have a higher rate of back pain and decreased incidence of improvement in their disability indices.⁶⁴

A pseudomeningocele is an extradural collection of cerebrospinal fluid (CSF). It is the result of CSF leaking through the dura usually as a result of a dural tear, and can be encased with an arachnoidal lining.⁶⁵⁻⁶⁷ A pseudomeningocele contains CSF and communicates with the subarachnoid space. A CSF fistula can also occur following an unintended durotomy.⁶⁸ The MRI findings include thecal sac communication, absence of mass effect, low T1 signal, and low T2 complexity.⁶¹ If not identified and

corrected, it can lead to wound swelling, headaches, radiculopathy and other symptoms of a dural tear.^{65,66} The best prevention of this is meticulous, watertight closure of any observed or suspected dural tear. Treatment of a pseudomeningocele involves CSF diversion by lumbar drainage. Treatment of CSF fistulas consists of oversewing the wound. These approaches have been shown to be effective treatments without neurological compromise. The gold standard for treatment is reoperation with watertight primary closure of the dural tear.⁶⁸

Arachnoiditis is the inflammation of the arachnoid mater, one of the three coverings of the central nervous system.^{69,70} Arachnoiditis leads to a myriad of clinical manifestations. One of which is chronic pain syndrome with a varying constellation of symptoms. There is no consistent and unifying symptom, as patients who suffer from the disease display differing symptoms with varying degrees of severity. Symptoms can range from mild tingling to severe motor involvement to, in rare cases, paralysis. In general, symptoms include tingling, numbness, motor weakness, radiculitis/radiculopathy, cramps, spasms, involuntary muscle twitches, and bowel, bladder, sexual problems. These symptoms may be transient or permanent. Patients with significant involvement can suffer severe disability secondary to their symptoms. Involvement largely tends to affect the lower nerve roots of the cauda equina, although reports at the cord level in the thoracic spine have been described.⁷¹⁻⁷³

The diagnosis of arachnoiditis is typically confirmed by advanced imaging including CT myelogram or MRI, which demonstrate abnormal grouping of nerve roots.^{71,74} One study grouped adherent nerve roots into three different patterns: centrally clumped, peripherally clumped (empty sac sign), or soft tissue infiltration of the arachnoid space.⁷⁴ If the appropriate constellation of symptoms is found in conjunction with these radiographic findings, a diagnosis of arachnoiditis may be made. If there are radicular symptoms, the disease may also be evaluated with EMG and its progression or remission may be followed.^{69,75}

The treatment for arachnoiditis focuses on multimodal pain relief. In addition, a multifaceted approach is often utilized that can include pain pharmacotherapy, exercise, physical therapy, and psychotherapeutic intervention. The prognosis varies depending on the severity of presenting symptoms.^{69,75}

During surgery, injury to the lumbar paraspinal muscles can occur due to muscle retraction.⁷⁶⁻⁸¹ Histologic and

biomechanical analysis of lumbar muscles following spine surgery has been performed before and after surgical retraction. Early injury is significantly correlated with retraction and operation time. Neurogenic changes have been observed for >10 months following surgery. Injury has also been directly correlated to both the duration and pressure of retraction and the extent of the exposure. Creatinine phosphokinase MM isoenzyme activity has been shown to be elevated following surgery. Longer retraction time has also been shown to result in a delay in recovery of muscle strength and a greater incidence of postoperative lower back pain. Studies show at least a 30% decrease in postoperative back strength following spine surgery at their 1-year post-op visit, suggesting a greater role for intensive physical therapy to regain physical strength.^{8,76-81}

Long-term Postoperative Factors

Long-term postoperative factors include worsening or progressive disease, scar tissue leading to epidural and peridural fibrosis, and pseudarthrosis.^{49,82} Progressive degenerative disease and degeneration of adjacent motion segments are all long-term factors causing increased pain.⁸² Following fusion, biomechanical forces are transferred to adjacent segments, increasing their risk of degeneration.⁸² Epidural fibrosis can cause recurrent radicular pain in the first 6 months following lumbar discectomy.⁸³ However, studies show conflicting findings in the relationship between scarring and postoperative pain. One study of MRIs taken at 6 months postoperatively shows that patients with greater peridural scar have a significantly greater increase in postoperative pain than patients with less peridural scarring.⁸³ However, another study shows no correlation between MRI findings of increased epidural scarring and recurrent postoperative pain.⁸⁴

Failure due to pseudarthrosis can be a significant cause of continued pain in the long-term following a spinal fusion.⁸⁵ This usually results in the return of both axial and radicular pain within the first year following surgery.⁸⁵ Risk factors include preoperative disc height, slip angle and segmental kyphosis.⁸⁶ Disc height >20% difference or with segmental kyphosis demonstrated an increased risk of pseudoarthrosis.⁸⁶ Anteroposterior and lateral radiographs can demonstrate typical findings of pseudarthrosis.⁸⁷ These include resorption of bone graft in the lateral gutters at 12 weeks, fatigue failure of posterior instrumentation,

radiolucencies around pedicle screws, or gaps between interbody graft or cages and vertebral endplates.⁸⁷ This can be identified through CT, plain radiographs including flexion and extension films.⁸⁵ Computed tomography and single photon emission computed tomography (SPECT) with CT can be used to identify screw loosening, nonunion around cages, and facet joint degeneration.⁸⁸ An SPECT with CT can also be used to improve the identification of nonunion and facet joint degeneration.⁸⁸ Surgical exploration is the gold standard for spinal nonunion.⁸⁷

PATIENT EVALUATION WITH FAILED BACK SYNDROME

Patient evaluation begins with a thorough history from the patient. It is important to understand the relation between preoperative and postoperative pain and any similarities and differences. In addition, timing of pain—i.e. whether immediate onset, subacute onset or onset of pain following a long period of relief—following lumbar surgery should be clarified. It is imperative to review the patient's past medical history and social history to rule out other diagnoses and to evaluate the patient for treatable patient factors and comorbidities (e.g. depression, substance abuse, workforce status, somatization, secondary gain, workman's compensation, and litigation). Psychosocial factors should be addressed prior to undergoing revision surgery. In addition, a thorough review of systems should be performed to rule out any other pathology, including infection or tumor.⁷

Physicians treating patients with continued chronic pain following lumbar surgery should have a low threshold for referral to psychologist or psychiatrist. Chronic pain and disability can worsen previous psychological comorbidities⁷ and psychological comorbidities can also worsen pain symptoms. Structured interviews and formal testing, such as the MMPI (Mean Minnesota Multiphasic Personality Inventory), are part of psychological workup for patients with psychological comorbidities or risk factors for psychiatric disorders. It is strongly predictive of surgical prognosis for patients with chronic pain.⁸⁹ However, one cannot rule out anatomic pathology based on psychological screening.

Physical Examination

The physical examination of a patient with FBS is similar to the preoperative patient evaluation. The examiner should

rule out Waddell signs.⁹⁰ These include superficial and nonanatomic tenderness, pain with axial compression or simulated rotation of the spine, negative straight-leg raise with patient distraction, regional disturbances that do not follow a dermatomal pattern, and overreaction to physical examination. In addition, a patient's gait, location of tenderness to palpation, joint range of motion (hip, knee, ankles), strength, sensation, peripheral pulses, upper motor neuron signs, and long tract signs can help evaluate and differentiate intraspinal from extraspinal sources of pain.⁷

Imaging

Imaging of the patient should include a review of available preoperative, intraoperative, and postoperative imaging. Radiographs should be used to evaluate spinal alignment and hardware loosening, subsidence, displacement, or breakage, and evidence of disease progression. Full-length standing radiographs should be obtained to evaluate sagittal alignment and the C7 plumb line. Dynamic radiographs can help evaluate for instability. Radiographs of other lower extremity joints can rule out concomitant orthopedic pathology.⁷ Magnetic resonance imaging with and without gadolinium is more effective for the postoperative spine than noncontrast MRI alone.^{7,91} It has up to 96% accuracy in differentiating epidural scar from disc material, including a recurrent disc herniation.⁹¹ Signal-intensity changes with epidural scar compared with disc material are subtle on T2-weighted images without contrast because disc material can be contiguous with the disc space. Following injection of contrast, scar enhancement is intense compared to disc material allowing for better delineation of scar from disc material. The addition of gadolinium can also help identify postoperative infection. It can help identify an epidural abscess and differentiate it from an adjacent compressed thecal sac. In addition, gadolinium can help to localize a paraspinal mass for a percutaneous biopsy and to identify an active infection.⁹²

The CT myelography is a valuable resource, especially when MRI is contraindicated with stainless steel instrumentation, with dynamic problems, and with scoliosis to better delineate the bony anatomy. Stainless steel instrumentation produces signal distortion and artifact that can compromise MRI clarity.⁹³ Plain CT is helpful for evaluation for pseudoarthrosis in combination with flexion/extension radiographs.⁹⁴ However, these imaging

studies still may not correlate with surgical findings⁹⁴ and radiographs may underestimate the fusion.⁹⁵

Electrodiagnostic studies including electromyograms (EMG) and nerve conduction velocity (NCV) are helpful in evaluating nerve root compression and locations of injury. They are useful in differentiating extraspinal impingement and pathology from intraspinal pathology and give an objective measure of nerve compression in patients with chronic pain.⁷

Laboratory evaluation can aid in workup for infectious. It should follow a thorough history and physical examination evaluating for constitutional symptoms. Patients usually note a different quality of pain after discectomy, which is an early symptom of diskitis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are the mainstays of laboratory evaluation. Although they are nonspecific, CRP peaks 2–3 days after spine surgery with rapid fall within 4–6 days and usually returns to normal by 14 days,⁹⁶ sooner than ESR.

Selective nerve root and facet joint blocks are helpful in localizing the source of the pain and can be both diagnostic and therapeutic. They are a safe and minimally invasive adjunct to a thorough evaluation. However, evidence is lacking in the effectiveness in the utility of joint blocks in assessing prognosis of repeat surgery.^{97,98} In addition, they usually provide only a temporary relief of pain and do not offer long-term pain relief.

Discography is extremely controversial. Provocative discography is an invasive diagnostic tool and should be used only for carefully selected patients after a thorough history, physical examination, and imaging. It consists of injection of contrast into the nucleus pulposus. It allows for assessment of disc morphology as well as patient response to pain provocation.^{99,100} A recent study demonstrated that lumbar discography had a negative effect on the discs tested.¹⁰¹ Discography resulted in a progression of degenerative changes, increased risk of disc herniations at the site of injection of contrast, loss of disc height and signal intensity, and increase in reactive endplate changes at 10 years postdiscography.¹⁰¹

TREATMENT OPTIONS

Nonoperative Treatment

Treatment of FBSS usually begins with nonoperative management. These include physical therapy, behavioral therapy, and specialized pain management. Neuropathic

pain can be treated by a wide variety of oral medications, including anti-inflammatory medications, tricyclic antidepressants, and anticonvulsants. In addition, physiotherapy, chiropractic therapy, acupuncture, muscle relaxation, and behavior modifications have been shown to be useful.¹⁰²

Interventional Pain Management

Interventional pain management options include adhesiolysis and epidural injections, medial branch blocks, and spinal cord stimulation. Epidural steroid injections (ESIs) are considered in patients who have failed to respond to less invasive treatment and prior to considering more invasive treatments.¹⁰³ Epidural steroid injections can be utilized for both diagnostic and therapeutic effects.² They have been shown to result in significant improvement in the visual analog pain scale at 3 weeks and 6 months. Success was defined as a 50% decrease in VAS score. The success rate was 84% at 3 weeks and 78% at 6 months. Epidural steroid injections significantly decreased the intensity of low back pain with FBSS.¹⁰⁴ A randomized controlled trial comparing injections of steroid to local anesthetic into the epidural space demonstrated that 60% of patients achieved >50% pain relief and disability reduction over 1 year with steroids.¹⁰⁵⁻¹⁰⁷ Improvements of these patients averaged 75% with an average of four procedures per year.¹⁰⁵⁻¹⁰⁷ Transforaminal steroid injection has also been shown to be effective for radicular pain following discectomy.¹⁰⁸ However, it has been shown to be effective in only 25% of patients with persistent radicular symptoms.¹⁰⁸ Most notably, however, it has been shown to result in significant pain relief in up to 43% of patients without a recurrent disc herniation.¹⁰⁸

Following spinal surgery, adhesions can form in the epidural space resulting in scarring and perineural fibrosis. The scar tissue can cause compression, inflammation, swelling, or decreased nutritional supply with resultant nerve root hypersensitivity.^{109,110} This can prevent steroid injections from travelling to their desired locations.¹¹¹ Spinal adhesiolysis, including percutaneous or endoscopic, is an option to treat epidural adhesions. It can be used to treat pain due to scarring.¹⁰⁹ Adhesiolysis can be mechanical with a wire-bound catheter or with placement of a catheter in the epidural space and infusion of high volumes of anesthetics, hypertonic or isotonic saline, and steroids.¹⁰⁹ Infusion of hyaluronidase can reduce the fibrosis.¹¹⁰ A recent systemic review demonstrated fair evidence that percutaneous adhesiolysis can be used to

relieve low back and leg pain for FBSS. The incidence of complications is low and usually self-limited.¹⁰⁹

Spinal adhesiolysis can be supplemented with epidural injections, allowing dispersal of corticosteroids throughout the prior surgical area. Epidural steroids with percutaneous adhesiolysis demonstrated a significant improvement in postoperative low back and leg pain and functional status over ESI alone.^{103,112} Studies have shown up to 50% pain relief, functional improvement, improvement of psychological status, and return to work. In addition, studies have shown strong evidence for short-term relief (i.e. <3 months), and moderate evidence for long-term relief.¹¹³⁻¹¹⁵ Direct medication administration via an intrathecal drug pump has also been shown to be helpful in reducing chronic or recurrent pain following spinal surgery. Although associated with high initial costs, it has been shown to be cost-effective if used for >12 months when compared with conventional therapies.^{102,116} Epidural steroid injection with and without adhesiolysis has been shown to offer short-term pain relief, but adhesiolysis significantly improved long-term pain relief in patients with FBSS.¹¹⁰ Another randomized trial comparing ESI combined with percutaneous adhesiolysis versus ESI alone demonstrated significant pain relief and functional status improvement in the disability score in 73% of patients with percutaneous adhesiolysis as opposed to only 12% with traditional ESI.¹⁰⁶ Average total relief was 42 out of 52 weeks with percutaneous adhesiolysis versus only 13 weeks for ESI alone.¹⁰⁶

Zygapophysial joint pain is an uncommon occurrence following lumbar surgery, specifically in discectomy.¹¹⁷ It can be a source of pain following lumbar surgery.¹¹⁷ Diagnostic and temporary treatment can be achieved through repeated medial branch blocks.¹¹⁷ Radiofrequency neurotomy has been shown to achieve significant pain reduction in these patients as well.¹¹⁷

Spinal cord stimulation (SCS) has been in use for >30 years and is used usually for neuropathic pain in the treatment of nociceptive pain.¹¹⁸ Spinal cord stimulation involves placement of percutaneous leads or electrodes in the epidural or intrathecal space with production of electrical stimulation by pulse generator over the spinal cord based on the patient's pain.¹ Spinal cord stimulation is postulated to work through the gate-control theory—through inhibition of transmission of nociceptive signals.¹¹⁸ It is related to the release of gamma-aminobutyric acid (GABA)-ergic and adenosine-related mechanisms in segmental spinal levels. Spinal cord stimulation reduces the

release of excitatory amino acids (glutamate, aspartate), and GABA release is augmented.¹¹⁸ However, most studies have been done on animals, and therefore there are no human studies regarding the mechanism of spinal cord stimulation on humans due to the complexity of its mechanism of action.¹¹⁸ A recent randomized controlled multicenter trial (PROCESS) trial of 100 patients compared medical management to spinal cord stimulation.¹¹⁹ Medical management included nonsteroidal anti-inflammatory medications, narcotics, antidepressants, and anticonvulsants/antiepileptics, nerve blocks, epidural steroid injections, physical and psychological rehabilitation, and chiropractic care. Spinal cord stimulation demonstrated improvement in leg pain, quality of life, and functional capacity, although 13 of the 42 patients treated with spinal cord stimulation required surgical revision.

Complications of spinal cord stimulation include electrode migration, loss of paresthesia, pain at implanted pulse generator incision site, infection or wound breakdown.¹¹⁹ Other complications include infection, lead migration, breakage, CSF leak and weakness.¹ In total, 31% (13) required surgical revision, the majority of which were in the first year,¹¹⁹ and 89% of patients were satisfied with SCS at 2 years.¹¹⁹ Another study demonstrated that permanent electrode placement resulted in at least 50% relief with reduced opiate analgesic requirement and was more effective than surgery.¹²⁰ However, those patients with objective anatomic surgical pathology, including neurologic deficit caused by surgical remediable compression, cauda equina compression, or gross instability requiring surgery, were excluded from the study.¹²⁰ A meta-analysis of 74 studies demonstrated a mean pain relief of 58% at 2 years follow-up. No predictive patient or technological factors were identified.¹²¹ Improvement in pain at longer-term follow-up has also been demonstrated. At 8.3 years, 75% of patients in one study demonstrated low back pain relief of >50%. Activities of daily living increased including ability to sit, climb stairs, and walk of >75%. Drug consumption decreased by >50% in 66% of the patients.¹²² Another study on 707 patients who received SCS therapy found no patient with permanent neurological deficits or deaths. Complications included lead migration (22.6%), lead connection failure (9.5%) and lead breakage (6%) requiring revision or replacement. Pain at the generator site (12%) and clinical infections (4.5%) were also noted. Patients with diabetes had an infection rate of 9% and those without diabetes had an infection

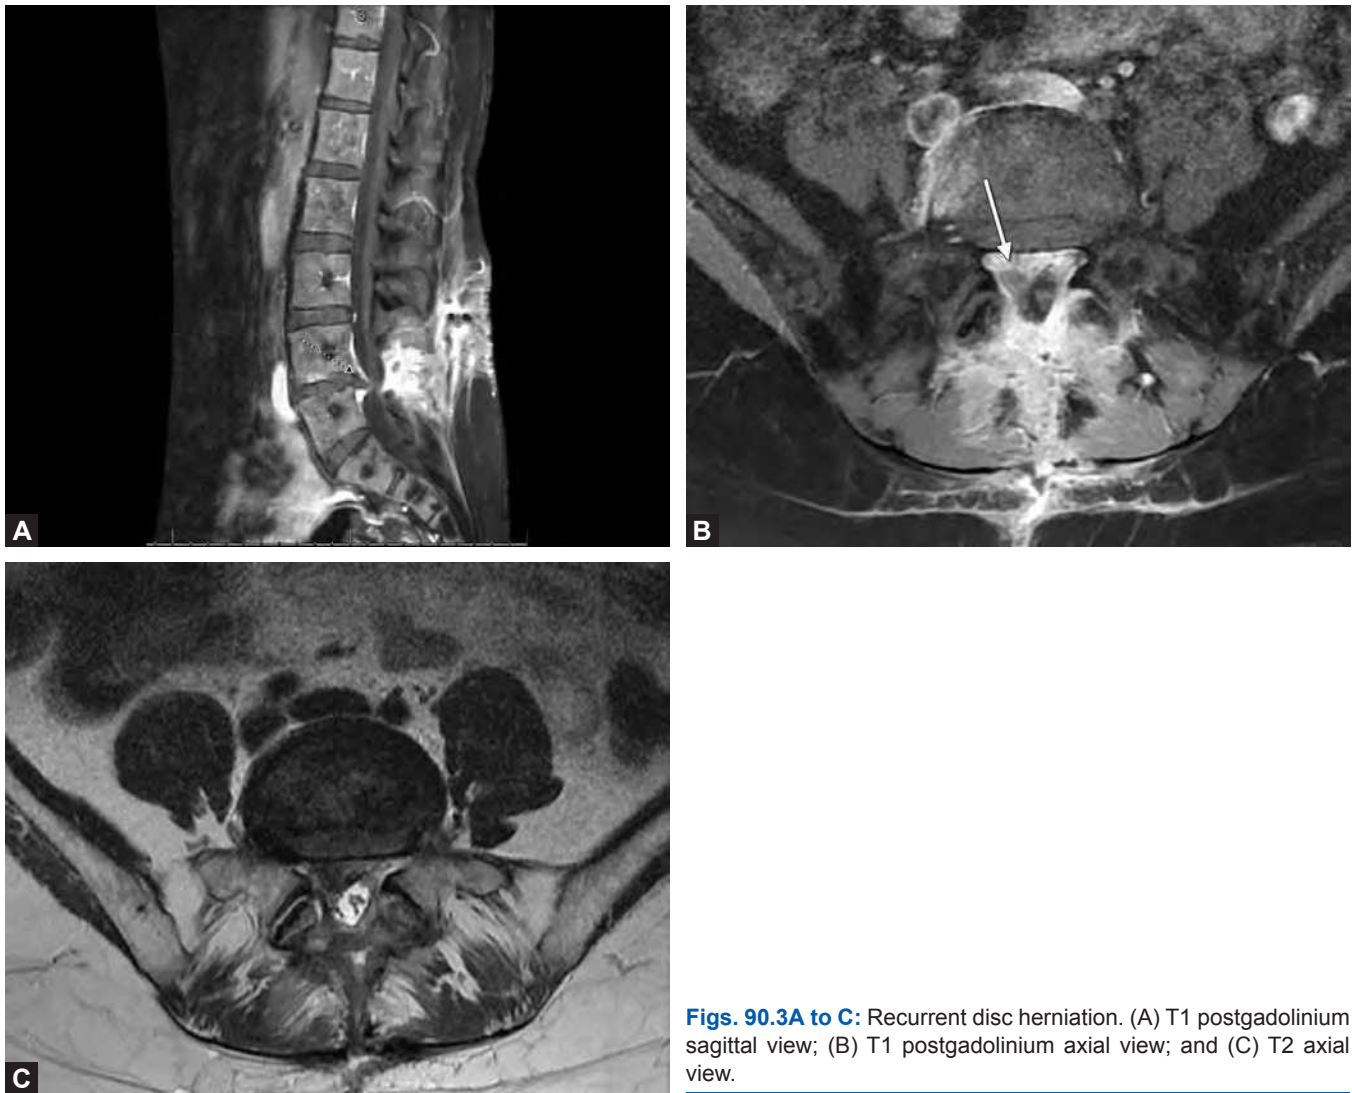

rate of 4%. Infections were treated with explanation and antibiotic therapy with no permanent complications.¹²³

Surgical Intervention

It is important to evaluate the patients for surgically correctable pathology as either the cause of their back pain or of their leg pain. Multiple pathologies may be evident on imaging, and therefore it is imperative to correlate diagnostic imaging findings with the patient's history and physical examination.² Flexion and extension radiographs, MRI with and without contrast, and CT myelograms are important tools in identifying possible pathology, including continued stenosis, recurrent disc herniations, instability, malignancy, and postsurgical complications including infection.² Results from revision surgery are poorer than the index procedure. Most patients who are deemed surgical candidates should have other diagnoses not related to the spine ruled out as their source of pain and should have failed extensive nonoperative treatment or have had only temporary relief from nonoperative interventions.⁷

Recurrent and residual spinal stenosis, most commonly foraminal stenosis, following lumbar surgery can be due to inadequate decompression, recurrent disc herniation, instability, scar formation, or adjacent level disease.¹²⁴⁻¹²⁶ Patients with recurrent stenosis demonstrate an increase in duration of symptoms and significantly less improvement in disability due to low back pain.¹²⁴ Reoperation for adjacent level disease was equal to reoperation at the index level.¹²⁴ No difference was seen between instrumentation, spinal canal diameter, or multilevel laminectomy between those patients who underwent reoperation and those who did not.¹²⁴ Moderate and marked regrowth demonstrates significantly decreased satisfaction, and is generally greater in those patients who do not undergo an arthrodesis procedure.¹²⁷ Recurrent lumbar stenosis has shown a significant improvement after revision lumbar surgery with improvement in low back pain, disability, and quality of life.¹²⁸

Recurrent disc herniation (Figs. 90.3A to C) as a cause of recurrent stenosis can result in significant leg pain and poor outcome following lumbar discectomy. Asymptomatic recurrent disc herniations have been shown in up to 25% of patients within the first 2 years.¹²⁹ However, the incidence of symptomatic recurrent disc herniations ranges from 5% to 15% and results in a significant increase in leg pain and disability.¹²⁹⁻¹³¹ Disc height loss was not seen in either symptomatic or asymptomatic recurrent

Figs. 90.3A to C: Recurrent disc herniation. (A) T1 postgadolinium sagittal view; (B) T1 postgadolinium axial view; and (C) T2 axial view.

disc herniations.¹²⁹ Risk factors for recurrent herniation include preoperative size and level of the disc herniation, male gender, a history of smoking, tall height and obesity, younger age, occupational repetitive lifting or vibration, and heaving lifting.¹³⁰⁻¹³³ Repeat discectomy should be considered only if the patient's radicular symptoms and physical examination findings correlate with radiographic imaging. Repeat discectomy for a recurrent disc herniation has been shown to require a significantly longer operating time.^{131,132} However, significant improvement and results similar to primary discectomy have been demonstrated with significant improvement in leg pain, quality of life similar to primary discectomy with no significant difference in hospital stay or postoperative clinical course. In

addition, age, gender, smoking, profession, and level of herniation did not affect clinical outcomes.^{131,132,134}

Instability, including postoperative spondylolisthesis or postoperative scoliosis following discectomy, laminotomy or lumbar decompressive laminectomy, has been shown to have an association with instability, most notably with significant resection of the facet joints (*see* Figs. 90.1A and B). Multilevel discectomies and foraminotomies also have been shown to result in increased sagittal motion.^{135,136} Significant resection of the spinous process, interspinous ligaments, and supraspinous ligaments during decompression increases the risk of segmental instability.¹³⁷ The posterior ligamentous complex acts as a tension band to stabilize the spine and can be lost during the index

lumbar surgery.¹³⁷ Preoperative indicators for instability included degenerative disc with radiographic changes, including traction spurs and loss of disc height, listhesis, and scoliosis.¹³⁸⁻¹⁴¹ Selective facetectomy is important in lumbar decompression and does not compromise the stability of the motion segment.⁴² However, total facetectomy and excision of the pars interarticularis result in spinal instability.^{42,138-140} The posterior elements should be spared as much as possible to avoid instability.¹³⁸ Symptoms include worsening back pain, radicular pain, increased motor weakness and sensory deficits.¹⁴² Radiographic changes include loss of disc height >30%, or spondylolisthesis on dynamic radiographs of >3 mm.^{142,143} Treatment involves reoperation with spinal fusion with or without secondary laminectomy.^{138,142} Significant improvement in postoperative pain was noted; however, improvement in motor and sensory symptoms was seen only in 50% of patients.¹⁴²

Flatback syndrome can result in significant postoperative morbidity (Figs. 90.2A and B). The goal is to restore sagittal alignment and recreate lumbar lordosis following lumbar spinal surgery.¹⁴⁴ Bracing alone has been shown to be ineffective in treating flatback syndrome.¹⁴⁵ In addition, surgical arthrodesis with no sagittal correction has poor long-term success.¹⁴⁴ Multiple corrective osteotomies can be used to correct sagittal imbalance. These include Ponte osteotomy, Smith-Peterson osteotomy, pedicle subtraction osteotomy, and vertebral column resection. These typically allow for shortening of the spine. Ponte and Smith-Peterson osteotomies allow up to 10° of kyphosis correction per level. A pedicle subtraction osteotomy allows for 30–40° of angular correction and is generally done at the site of maximum deformity. Vertebral column resection results in complete discontinuity of the proximal and distal aspect of the spine, allowing for >60% local sagittal and coronal plane correction.^{47,146-148} Flexible kyphosis following multilevel laminectomies can be treated with spinal arthrodesis alone.¹⁴⁵ Patient with severe and stiff kyphosis can be treated with corrective osteotomy and spinal arthrodesis.¹⁴⁵

Pseudoarthrosis following lumbar surgery can be treated with iliac crest autograft and pedicle screw instrumentation. Revision surgery demonstrates a high rate of solid fusion, but did not always correlate with improved clinical outcomes and has variable outcomes depending on the diagnosis.¹⁴⁹ In patients with degenerative disc disease, revision surgery demonstrates only a 50% improvement in their symptoms. In patients with

spondylolisthesis, however, revision surgery demonstrates a 64% improvement in their postoperative ODI scores following successful repair of their nonunion.¹⁵⁰ Revision lumbar arthrodesis for symptomatic pseudoarthrosis can improve low back pain, disability, and quality of life.¹⁵¹ Improvement continued to be noted at 2 years following revision surgery.¹⁵¹ Patients were independent of narcotics on average at 12 months postoperatively and return to work was 4 months postoperatively. No patient had repeat pseudoarthrosis at 2 years.¹⁵¹ However, no significant improvement was noted in the mental component score or self-rating depression scale score and it was noted that mental health symptoms may be more refractory to revision surgery.¹⁵¹

Overall, visual analog scores for back pain and Oswestry Disability Index were improved significantly with revision decompression and instrumented fusion for adjacent segment disease, pseudoarthrosis and recurrent stenosis.¹²⁸ Revision surgery for these diagnoses resulted in significant improvement in low back pain, disability, and quality of life.¹²⁸ They further evaluated the cost-effectiveness of revision surgery for these diagnoses and found a mean 2-year cost of \$80,594 per quality-adjusted life year.¹⁵²

Occasionally patients may note significant back pain despite any evidence of pathologic findings on history, physical examination, or radiographic findings and with evidence of a solid fusion. Patients with tenderness to palpation along the hardware can undergo anesthetic injections along the hardware at the sites of greatest pain.¹⁵³ Significant pain relief following anesthetic injection has been shown to be a predictor of significant pain relief following implant removal.¹⁵³ A significant decrease in pain was noted in these patients following implant removal with only a small incidence of complications.¹⁵⁴ Although a majority of patients note significant pain relief and would repeat the removal of hardware operation, only 12% in one study noted complete pain relief.¹⁵⁴ In addition, patients should be followed for worsening of their deformity following implant removal.¹⁵⁵ A significant number of patients initially treated with scoliosis had worsening of their coronal curve and a more frequent worsening of their sagittal curve following implant removal.¹⁵⁵ This was more common in patients with a larger preoperative sagittal kyphosis and did not correlate with the reason for implant removal or postoperative time between the initial surgery and the implant removal.¹⁵⁵

Motion Preservation

Alexander R Vaccaro

Biomechanics of Motion Preservation Strategies

Hans-Joachim Wilke

Snapshot

» Posterior Implants

» Anterior Implants

INTRODUCTION

For many years, the “Golden Standard” in spinal surgery in order to treat different spinal pathologies, such as fractures, instabilities or degeneration, was to fuse motion segments by bridging the treated segment with stiff implants. The goal was to stabilize the spine as good as possible to allow fast bony fusion, on the basis of the maxim “the stiffer the better”. In many patients, the outcome of these surgical interventions was quite good; however, in some cases, degeneration in the adjacent segments was observed.^{1,2} Although it is still not proven,^{3,4} it was quickly hypothesized that the fusion is responsible for this so-called “adjacent level syndrome” because the stiff region in the spine leads to an overload in the segments above and below.⁵

Particularly in the last decade, nonfusion technologies in spinal surgery have gained more and more popularity.⁶ Constantly new ideas are created and turned into new products. Each idea has its own philosophy with the principle goal to restore and maintain the disc height and/or original mobility of a healthy segment. Furthermore, these ideas allow preserving at least partially some spinal structures, which are sacrificed with spinal fusion.

These motion preservation strategies have led to different implant categories, which can be divided into posterior or anterior devices (Fig. 91.1).

- The goal of posterior devices is to stabilize the treated segments but preserve the disc or just to unload or to replace the facet joints. The most important represent-

atives are flexible stabilization systems such as dynamic fixators, interspinous implants that are just placed between the spinous processes or implants to replace the facet joint or the entire posterior complex.

- The anterior technologies are total disc prostheses, nucleus replacement devices or ideas to seal or close a hole in the annulus.

POSTERIOR IMPLANTS

Dynamic Stabilization Systems

Internal fixators are generally used to stabilize a degenerated segment and to promote fusion, after the disks are replaced either by intervertebral cages, allografts or autologous bone grafts. However, from a clinical point of view it may not be desirable to sacrifice a moderately degenerated disc and to cause donor site morbidity for the use of autologous bone grafts.

Therefore, already in 1992 the so-called ligamentoplasty was suggested, a technique in which the pedicle screws were tightened with polyester ring bands.⁷ With this technique, it was possible to maintain the disc and the physiological lordosis in the lumbar spine. It was shown that the instability, which is created by a laminectomy and the partial removal of the facet joints, could be reduced in all directions with this technique.^{8,9}

A few years later, the first dynamic fixators were introduced, which connect the screws with flexible longitudinal elements instead of rigid rods (Figs. 91.2A and B).

Fig. 91.1: Representative pioneering implants of the different categories for motion-preserving technologies in spinal surgery.

The first clinically used implant of this type was the Dynesys Spinal System (Centerpulse Orthopedics Ltd, Winterthur, Switzerland) to provide spinal alignment and dynamic restabilization up to five contiguous levels from L1 to S1 while preserving the disc as well as the facet joints (Dynamic Neutralization).¹⁰⁻¹² It is composed of pedicle screws, polyethylene terephthalate cords and polycarbonate urethane spacers. The spacers are placed bilaterally between the pedicle screw heads to withstand compressive loads. The cords are running through the hollow core of the spacers and stabilize the construct by a tensile preload.

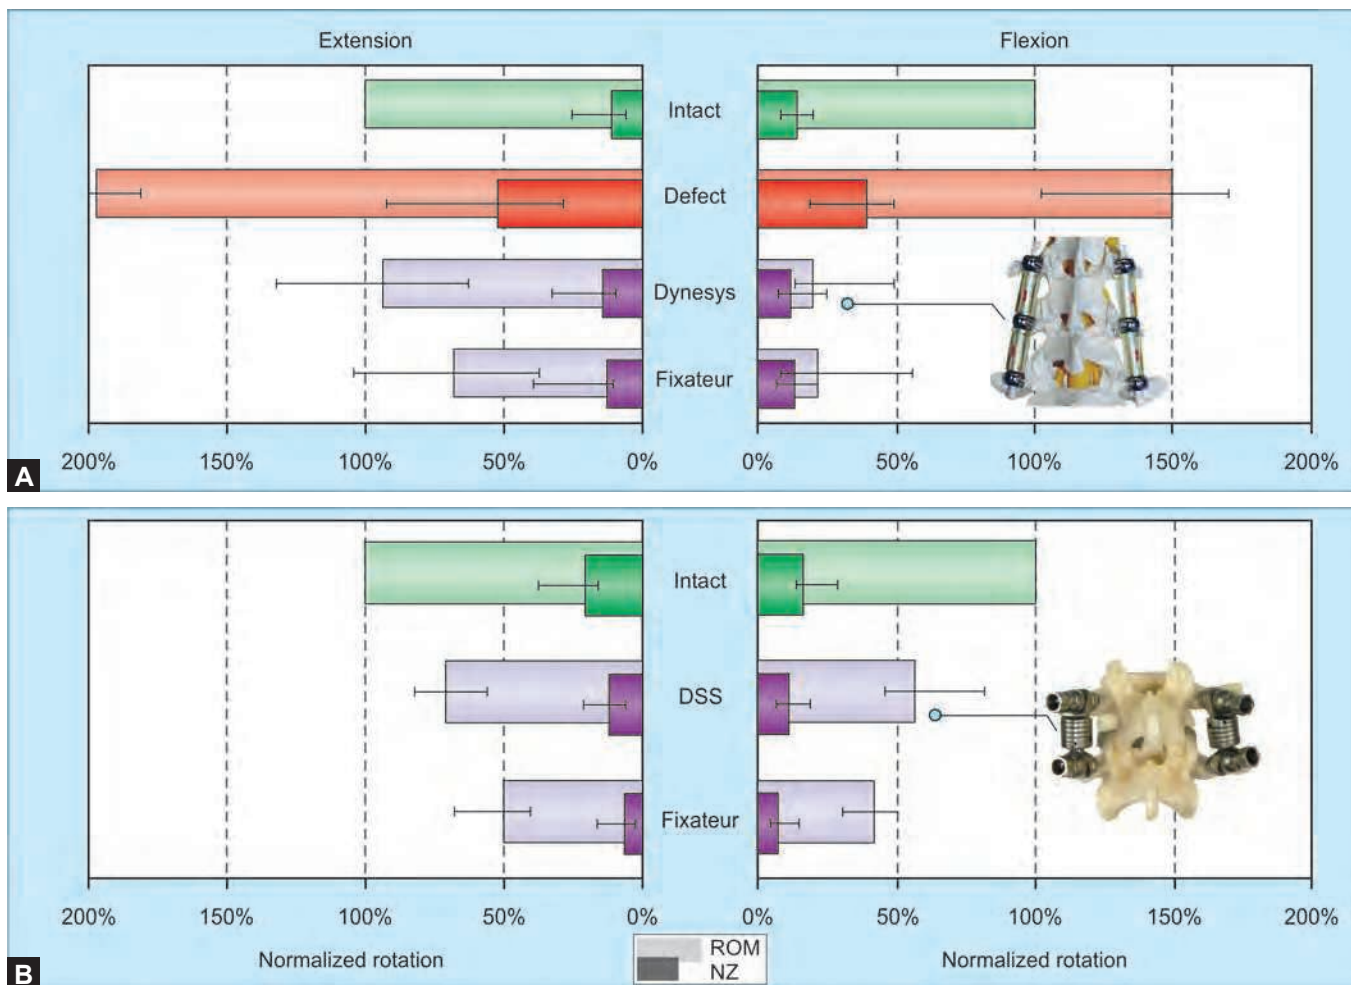

Our own biomechanical in vitro investigations have shown that a segment with a large defect could be stabilized again with the implants in most directions (Figs. 91.3A to F).^{13,14} The Dynesys stabilized the spine significantly but was only slightly more flexible than the internal fixator, most pronounced in extension. In flexion, however, the Dynesys provided the same stiffness as the internal fixator, because both rods act as tension band posteriorly of the spine. In axial rotation, there was a big difference between both implants. The internal fixator was able to restore the normal range of motion, whereas the Dynesys allowed for larger motions, which were even above the normal values of intact segments. If

the spacers are too long, the Dynesys acts to distract the facet joints; that is, the range of motion in axial rotation increases with greater spacer length.¹⁵

As this concept of dynamic stabilization *per se* was considered as superior to former implants and widely accepted, a large number of implants followed and are still in the development phase.^{16,17} They allow more flexibility but at the same time control the stability of the motion segment through joints, springs, or complex spring-damping systems (Fig. 91.3).¹⁸ The problem is that it is still not known how much flexibility or stability is optimal for these kinds of implants.

Interspinous Implants

Interspinous implants are placed as spacers between the interspinous processes. The goal is to unload the facet joints and the disk, to restore foraminal height and to provide sufficient stability, especially in extension, but still allow motion in the treated segment. They are primarily used for posterior lumbar spinal pathologies such as spinal stenosis or facet joint arthritis, although the indications are not yet clearly defined because scientific evidence is still lacking (Figs. 91.4A to D).^{19,20}

Figs. 91.2A and B: Results of range of motion (ROM) and neutral zone (NZ) in flexion and extension normalized to the intact state. The test of the upper diagram was performed with six L3–4 segments with a defect (dissection of the supraspinous ligament, interspinous ligament, flavum 1, tenotomy of facet joint capsules and a nucleotomy).^{13,14} The test in the lower diagram was performed with six L2–3 segments without a defect.

Because the implantation is simple and has only a low risk for the patient, this technology became quickly very popular. More and more interspinous implants appeared on the market. Some of these implants are, e.g. pierced through the interspinous ligament to preserve the supraspinal ligament and secured in place with two lateral wings or with ligatures around the processes. Other implant variations require cutting the supraspinous ligament to enable the placement of the implant. To compensate for the putative function of the sacrificed ligaments, these implants are usually fixed with bands or cords on the spinous processes or the wings are crimped to the spinous processes.

Most spacers mainly prevent spinal extension and unload the disk, but at the same time allow physiological movement in all other directions. U-shaped implants

may provide an additional damping effect due to the deformation of their spring-like shape and their mobile center of rotation during motion. Our own biomechanical in vitro experiments have shown that four evaluated interspinous implants had a similar effect on the three-dimensional flexibility of the treated segments.²¹ They significantly stabilized the unstable segment in extension and restricted the range of motion to about half of that of the intact state and unloaded the disc (Fig. 91.5). In the other planes, however, especially in lateral bending and axial rotation, the values of range of motion did not significantly change compared to the values of the destabilized state. Similarly, the load on the disc was decreased significantly with all implants during extension but not in flexion, lateral bending and axial rotation.

Figs. 91.3A to F: Different principles for dynamic or semirigid fixators or couplers that are in clinical use: (A) Polycarbonate urethane spacers and polyethylene terephthalate cords; (B) elastic elements in the rods; (C) screw fixations with hinge-joints; (D) spring elements; (E) complex spring-like elements; and (F) spring-damper systems.

Total Posterior Element Replacement System

Facet joint arthritis can occur independently of disc degeneration. Therefore, there are implants that replace the entire posterior complex of a spinal segment or only the articular facets.²² Most systems are fixed with four transpedicular screws. Experimental investigations have shown that some implants may mimic almost the ideal range of motion in flexion, extension, and lateral bending. The geometry of the implant is even able to control the physiological range of motion in axial rotation with respect to posture, i.e. more in flexion and reduced motion in extension.²³

New implant ideas even try to only replace the articular surfaces of the small joints. These small implants are anchored with pins in the joints. However, little is known about such approaches so far. Before they can be used in clinical application, experimental studies must prove that these implants permit the desired movement, guarantee

Figs. 91.4A to D: Interspinous implants.

in the long term a reliable fixation, and that only a slight abrasion occurs.

All posterior devices maintain motion and some loading of the disk. It may be assumed that physiological loading of the disk has advantages to the disc structures and its regenerative potential. This physiological loading may be expressed by the bulging of the disk. In a study using a three-dimensional laser scanning device,^{24,25} it could be shown that the more dynamic a posterior stabilization device is, the closer the disc behaves biomechanically with

the disc in a healthy segment (Fig. 91.6). The value of these differences, however, still has to be discussed with caution.

ANTERIOR IMPLANTS

Total Disc Prostheses

Total disc arthroplasty (TDA) has evolved to an extremely exciting technology over the last decade.²⁶ After the initial enthusiasm, some disillusion has also spread, because the long-term results are not as good and reliable as hoped, and it has become evident that the development of an artificial disc is a big challenge.²⁷⁻²⁹ Nevertheless, the number of disc prosthesis products on the market has grown rapidly in the recent years. Until now, many proposed solutions were fairly simple, compared to a real intervertebral disk, which has a very complex structure.³⁰⁻³² Most of the current designs are based on an articulating ball-and-socket concept, reminiscent of the conventional implant systems that were popular for small joint replacement. The various prosthesis designs attempt to control the movement directly by the geometry of the articulating surfaces, to mimic the physiological center of rotation with constrained implants or to allow a fully unconstrained motion of the individual prosthesis components in devices with mobile cores (Figs. 91.7A to D). The current trend for disc implants is to design them in such a way that the three-dimensional physiological stiffness of the natural disc is reproduced. Therefore, the

Fig. 91.5: Interspinous implants restrict motion and unload the disc in extension.

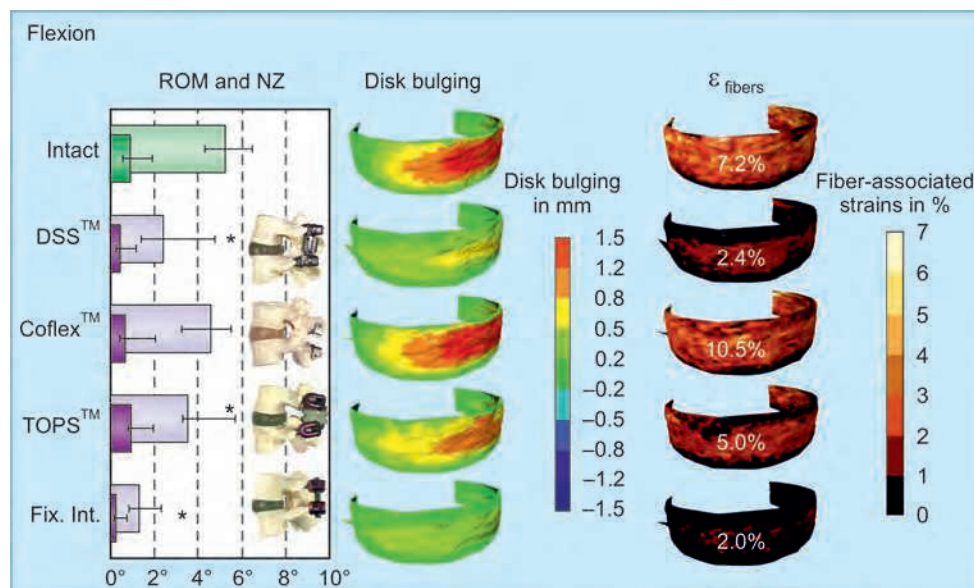

Fig. 91.6: All posterior devices allow more motion than the internal fixator and thus restore more loading on the disk, which is also expressed in larger strain in the annulus fibers.

Figs. 91.7A to D: Classification of total disc prostheses: (1) completely controlled kinematic (constrained), (2) partially controlled kinematic (semiconstrained), (3) no control through implant, i.e. all 6° of freedom possible (unconstrained). (A) Noncongruent gliding surfaces; (B) Two different pairs of gliding surfaces; (C) Deformable core; and (D) Simulation the physiological structure.

types of prostheses that are currently available can be categorized into implants with a fixed center of rotation, implants that are incompressible with a mobile center of rotation, and compressible implants with a mobile center of rotation.^{6,31,33-36}

In our *in vitro* studies, a finite element calculation simulating the influence of different design philosophies on cervical implant performance was compared. Overall, it can be summarized that unconstrained prostheses increase segmental lordosis more than semiconstrained ones.³⁷ Resection of the posterior longitudinal ligament further exaggerates this increase; however, its effect can be avoided by using a taller implant.³⁸ The prosthesis height seems more crucial than the preservation of the posterior ligament in terms of stability. The location of the center of rotation in a semiconstrained prosthesis did not alter the magnitude of range of motion. This, however, cannot be extrapolated to a change in implant position, which probably has a strong influence.

It can be speculated that the center of rotation seems to be of special interest. The principles can be investigated best with well-validated or better calibrated finite

element models (Figs. 91.8A and B). Our own calculations with unconstrained disc prostheses and semiconstrained versions that allow translations of the core in lower end-plate of the implant in both the anteroposterior and the laterolateral direction or a fixed core showed that all implant designs demonstrated a moving center of rotation.³⁹ Except for axial rotation, the unconstrained and constrained configurations mimicked the intact situation. In axial rotation, only the semiconstrained implant that allowed translation of the core reproduced the intact behavior. Results partially support our hypothesis and imply that different implant designs do not lead to strong differences in the range of motion and the location of the center of rotation. In contrast, facet forces appeared to be strongly dependent on the implant design.³⁹ However, due to the great variability of facet forces reported in the literature, together with our results, it could be speculated that these forces may be more dependent on the spines geometry rather than a specific implant design.

The greater the number of artificial disks that are implanted in one patient, the greater the correlation of flexion and extension motion is to the intact condition.⁴⁰ Deviations from optimal implant position lead to unfavorable kinematics, high facet joint forces, and even to lift-off phenomena. Therefore, multilevel TDA should, if at all, only be performed in appropriate patients with good muscular conditions and by surgeons who can ensure optimal implant positioning.

Nucleus Replacement Implants

If the disc is not strongly degenerated, i.e. the annulus is still more or less intact, then nucleus implants may be used as an alternative to a total disc prostheses.⁴¹ This concept has the advantage that existing anatomical structures can be preserved, e.g. the annulus, the end-plates of the vertebral bodies and the ligaments. Besides maintaining mobility, a nucleus replacement has the potential to restore disc height and thereby the nominal stresses and strains of the collagen fibers in the annulus. From a historical perspective, in the 1950s and early 1960s the nucleotomized cavity was refilled with polymethylmethacrylate (PMMA), silicone or stainless steel balls if a nucleus implant was desired.⁴²⁻⁴⁴ The intention of nucleus replacement is to restore the disks biomechanical function, prevent pain and further disc degeneration. The implants also should be biocompatible and nontoxic. Because of the different materials that are used today, it is possible to divide nuclear implants into mechanical, polymer and tissue engineered implants (Fig. 91.9).⁴⁵

Figs. 91.8A and B: (A) SB Charité III disk—representing an unconstrained design. (B) Slide disk—also representing an unconstrained design, but additionally the core can move almost freely within the transversal plane.

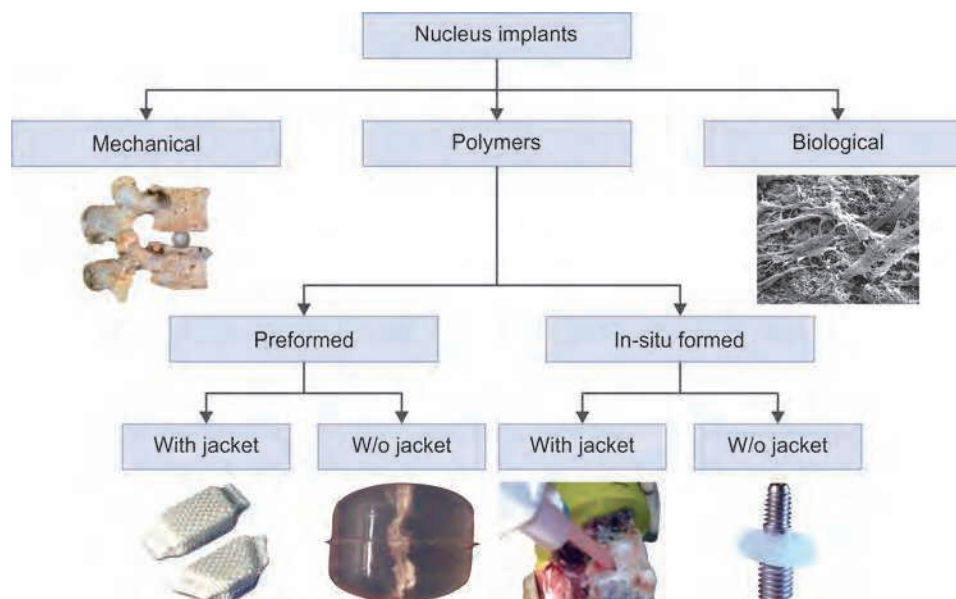

Fig. 91.9: Classification scheme for different nucleus implants concepts.⁴⁸

In our own studies, we were able to show that the original flexibility and disc height of a denucleated L4-L5 motion segment can be restored with the implantation of a nucleus implant.⁴⁶ However, the kinematics, i.e. the quality of the motion, can hardly be predicted. It has been

shown that an implant may restore ideal coupled motion patterns, or reproduce a hinge joint motion with negative effects on facet joint motion.⁴⁷

Definitively the biggest problem with nucleus arthroplasty is the risk of extrusion (Figs. 91.10A and B).⁴⁸

Figs. 91.10A and B: Two video sequences of nucleus implant extrusion. (A) A nucleus replacement implant based on a two-component silicone gel during a cyclic loading test. After 20,000 load cycles, the implant was completely extruded; (B) A tissue-engineered nucleus replacement implant, which basically consists of condensed collagen type-I matrix, extruded already during a flexibility test (lateral bending) in a spine tester.

Almost all nucleus devices, which were tested *in vitro* in our laboratory, could be extruded in our cyclic loading setup. The tissue engineered implants made of collagen matrix were squeezed out after only a few loading cycles if the hole produced by the nucleotomy was in the range of 6–7 mm.⁴⁸ Textile implants proved to maintain their stability longer, but still were extruded with a low number of load cycles. A similar finding was found with *in situ* formed implants. Some of them could be provoked to extrude, while some maintained their position up to 100,000 load cycles. Unfortunately, it could not be clarified whether this problem could be explained by the shape or the size of the implant or the size of the nucleotomy. Only the knitted prosthesis demonstrated reasonable stable fixation, because the filaments of the implant subsided and thus attached mechanically into the cartilaginous part of the endplate.⁴⁹

Methods of Annulus Sealing

If nucleus implants are to remain stable within the disc or if a recurrent disc herniation is to be prevented, reliable sealing techniques are required that can withstand extremely high pressures of at least 2.3 MPa (333 PSI) of hydrostatic pressure.⁵⁰ Considering how difficult it is to close a hole in a car tire where a pressure of 0.23 MPa (33 PSI) is present, it is challenging to overcome pressures that are 10 times greater than that in the human disk.

Suturing and gluing the annulus defect increase the number of load cycles until an implant is extruded.⁵¹

If gluing and suturing are combined, it appeared to allow up to 40,000 load cycles before an extrusion occurred; however, a sufficient sealing could not be guaranteed. Until now, most nuclear replacement implants have not proven to be reliable and have been taken off the market. Therefore, it is extremely important to test these implants with an adequate testing model. We established a human herniation model that reliably produced and generated a nucleus implant extrusion during cyclic loading, which could only be guaranteed in specimens with minimal disc degeneration.⁵² The only sealing device that has shown to work adequately is the Barricaid implant (Intrinsic Therapeutics), which appears to prevent the nucleus from reherniating under our testing conditions (Figs. 91.11A and B). These findings reaffirm the importance of critically investigating new annulus closure devices and nucleus replacement techniques before they can be used clinically in a patient.

CONCLUSION

Each technology designed to preserve spinal motion behaves in its own unique way biomechanically. In order to prove the potential advantages of an implant, it should be tested in *in vitro* experiments before it is applied clinically in a patient. Unfortunately, only few prospective and controlled clinical trials (class I or II evidence) are available on these devices, or the follow-up time clinically is too short for a definitive understanding of the devices performance and durability.

Figs. 91.11A and B: Annulus sealing with the Barricaid implant.

Despite the limitations of biomechanical in vitro testing and complementary finite-element-calculations, such investigations may provide interesting results that can stimulate academic discussion. Sometimes these tests demonstrate that the implants behave as suggested. Sometimes the results help to optimize the technology. Sometimes it can be shown that specific features do not lead to significant differences in performance, and sometimes the results do not support the promised behavior of an implant design. Therefore, preclinical tests should always be performed using appropriate methodology to truly understand the limitations of a spinal implant.

ACKNOWLEDGMENTS

This chapter cites a series of different experimental studies that were carried out by different teams. Therefore, I would like to acknowledge all coworkers who actually did the work in these studies: Werner Schmölz, Jörg Huber, Thomas Nydegger, in the DYNESYS study; Jörg Drumm, Kim Häussler, Annette Kettler, and Karin Werner in study about interspinous implants; Werner Schmölz, Hendrik Schmidt, Karin Werner, Michael Tauber, Lutz Claes in the TOPS study; Balkan Cakir, Werner Schmoelz, René Schmidt, Wolfhart Puhl, Marcus Richter investigated the total disc prosthesis; Annette Kettler, Marcus Mohr, Sinead Kavanagh, Allison Bain, Britt Norton evaluated the prosthetic disc nucleus; and Frank Heuer and Cornelia Neidlinger-Wilke supported the study with the tissue engineered nucleus. Anulus Sealing was studied with Frank Heuer and Lena Ressel.

The studies were supported financially by the following companies: DePuy Spine, Impliant Ltd., Raymedica, Paradigm Spine, Synos Foundation, Ulrich medical, ARS Arthro, and Intrinsic Therapeutics.

Posterior Pedicle-Based Dynamic Stabilization of the Lumbar Spine

- » Summary of Our Results

DEFINITION

Posterior pedicle screw-based dynamic stabilization devices (PDS) are posterior, more or less flexible implants, which originally were intended to control motion and/or load bearing of the motion segment, in order to address instability and the resultant back pain.¹ However, back pain was never really well treated with such devices. Excellent results are obtained when a symptomatic spinal stenosis with degenerative spondylolisthesis is decompressed and stabilized with such a PDS.

HISTORY

Graf developed the first system in 1992 to stabilize and treat painful motion segments.² It used braided polyester cables looped around screws to provide stability while allowing some motion. Several reports have been published on the clinical results of this device: the outcomes have been inconsistent. Later on, Gilles Dubois developed the Dynesys system marketed by Zimmer.³ This system uses semirigid polyurethane spacers over a polyethylene cord put under tension and connected to pedicle screws. This system also was intended to treat low back pain. The clinical results, however, were mixed. Grob et al. published a retrospective study on 50 patients who were treated with the Dynesys system for symptomatic degenerative disc disease or stenosis with associated instability.⁴ Back and

leg pain improved in 67% of patients; however, functional capacity only improved in 40% of the patients with a high rate of reoperation (19%). Grob, therefore, stopped using these implants. In Switzerland, Dynesys was not only used for 1–2 levels, but some surgeons used it for stabilization of 4–5 levels, with sometimes deleterious results (unpublished data).

Today, a variety of semirigid pedicle-based implants have been introduced, including AccuFlex (Globus Medical, Inc.), CD-Horizon Legacy PEEK rods (Medtronic), ExpEDIUM PEEK rod (DePuy Synthes), Scient'X's Isobar, Stabilimax NZ device (Applied Spine Technologies, Inc.), and the Cosmic posterior dynamic system (Ulrich GmbH & Co. KG) to name a sampling. The most extensively investigated device, however, is the Dynesys system.

OWN EXPERIENCE

Our experience was similar to the one of Grob et al.⁴ We never implanted Dynesys to treat low back pain, but had to remove Dynesys implanted by others because of persistent pain after stabilization with this system. During removal of such implants, we discovered that some motion segments bridged by the so-called dynamic system were spontaneously fused. We, therefore, thought that these implants could be used for stabilization of degenerative spondylolisthesis in addition to decompression of a spinal stenosis, making bone grafting unnecessary. In 2000, we

evaluated our first series of patients, which we published in 2006 with a minimum follow-up period of 2 years.⁵ The same group of patients were followed up at 4 years.⁶ Currently, we are reviewing our patients at 10-year follow-up. Our results have been satisfactory and therefore we apply pedicle-based dynamic stabilization in addition to decompression as our standard stabilization technique for degenerative spondylolisthesis, when decompression has to be performed because of symptomatic spinal stenosis.

Meanwhile, several other publications have shown that pedicle-based dynamic systems may be used with excellent results for the stabilization of degenerative spondylolisthesis, without any bone supplementation, making surgery easier for the patients and for the surgeon.⁷⁻⁹

INDICATION FOR SURGERY

We use the dynamic pedicle stabilization technique exclusively for the stabilization of degenerative spondylolisthesis with symptomatic spinal stenosis undergoing surgical decompression. All our patients have spinal claudication unresponsive to nonsurgical treatment (nonsteroidal inflammatory drugs, epidural steroid injections, physiotherapy, etc.).

SURGICAL TECHNIQUE

Decompression

The most important part of our surgical treatment is the proper decompression of the spinal canal. All stenotic levels are decompressed. We use the classical midline approach. The laminae and articular masses are exposed on both sides. The interspinous ligament and the *ligamentum flavum* of the segments to be decompressed are removed. Usually, a few millimeters of the cranial part of the caudal lamina as well as inferior parts of the cranial lamina are removed. We use an interspinous spreader to widen the interspinous space and allow easier decompression. The dura and the exiting nerve roots are fully decompressed, the roof of the lateral recess is removed to the medial pedicle border, and the caudal foramen is enlarged if necessary. The cranial foramen is decompressed as well if necessary.

Stabilization

After thorough decompression of all stenotic segments, stabilization is performed only at the level of the degenerative spondylolisthesis (Figs. 92.1 and 92.2). We use the dynamic system exclusively for the stabilization of

degenerative spondylolisthesis at one and at maximum two levels. The pedicle screws are inserted under fluoroscopy and the dynamic connectors (polyurethane sleeves for the Dynesys system, PEEK rods for the ExpEDIUM system) are mounted. To allow proper insertion of the Dynesys sleeves or PEEK rods, the degenerated and hypertrophic joints of the spondylolisthetic segment must usually be trimmed somewhat. No distraction or compression is needed, and most importantly no attempt to reduce the degenerative spondylolisthesis is performed. This would destabilize the motion segment and screw pull-out could be the result. No bone grafting is performed. The wound is closed in layers over three drains—two subfacial and one subcutaneous.

Postoperative Management

The patient is mobilized the first day after surgery with a soft lumbar orthosis for 3 months to allow healing of the soft tissues and bony incorporation of the screws. An X-ray is performed at 3 months. At this stage, the patient is allowed to start with his normal daily activities. Usually, no physiotherapy is needed.

SUMMARY OF OUR RESULTS

At 2 and 4 years, visual analogue score and walking distance improved significantly ($P < 0.001$). Radiographically, spondylolisthesis did not progress and the motion segments remained stable even in three patients who showed slight screw-loosening at 2- and 4-year follow-up. At 4-year follow-up, 47% of the patients showed some degeneration at adjacent levels. Overall, patient satisfaction was very high as 95% would opt again for the same treatment.

At 10-year follow-up (range 10–13 years), spondylolisthesis did not progress and the motion segments remained stable. Nearly two-thirds of the patients, however, now showed a slight to moderate increase in adjacent segment degeneration and 8% of the patient population had required further surgery because of symptomatic adjacent segment degeneration (Figs. 92.3A and B). However, 90% of patients still would undergo the surgery again.

DISCUSSION

In our experience and based on the literature, dynamic pedicle-based stabilization of lumbar spinal segments is not successful in the treatment of low back pain. However, it can be successfully used for the stabilization of degenerative spondylolisthesis when spinal stenosis has to be

Figs. 92.1A to C: An 80-year-old woman with typical spinal claudication. She can only walk about 50 m. After this distance, the pain in the leg is so intense that she has to sit down. Also, her legs become very weak during walking. The myelogram (A) shows spinal stenosis L2/3 and stenosis at the level of the degenerative spondylolisthesis L3/4. A decompression L2/5 was performed and the degenerative spondylolisthesis L3/4 was stabilized with Dynesys (B). Two years after surgery, the patient is pain free and the implants are stable (C).

Figs. 92.2A and B: A 79-year-old woman with spinal claudication with leg pain L5 on both sides for 2 years while walking. Walking without help is only possible indoors; outdoors she can walk slowly for 500 m with a wheeled walker. The magnetic resonance imaging (A) shows a marked spinal stenosis at the level of the degenerative spondylolisthesis L4/5. The stenosis L4/5 was decompressed and the degenerative spondylolisthesis L4/5 stabilized with Expedium Peek rods. The 2-year follow-up (B) shows stable implants.

Figs. 92.3A and B: A 69-year-old man, 10 years after decompression of a spinal stenosis L4/5 and stabilization with Dynesys because of the degenerative spondylolisthesis. The patient was pain free during 9 years after surgery and presented to the 10-year follow-up with some leg pain and leg weakness while walking for the last 2 months. The X-rays (A) show stable implants and a spontaneous posterolateral fusion L4/5 (no bone grafting had been performed at index surgery). The myelo-CT (B) shows a spinal stenosis L3/4, the level above the stabilized segment.

treated surgically. Compared to posterior fusion techniques using rigid implants, PDS does not need bone grafting; therefore, PDS is quicker and less invasive since there is no donor site morbidity.

Total Facet Replacement

Darren R Lebl, Frank P Cammisa, Federico P Girardi, Alexander R Vaccaro

Snapshot

» Total Facet Replacement Devices

INTRODUCTION

The functional spinal unit (FSU) consists of the intervertebral disc, the cranial and caudal vertebrae, the interconnecting ligaments, and two facet joints. While the motion-preserving concept and clinical experience with lumbar total disc replacement (TDR) have evolved over the past several decades, total facet replacement (TFR) is relatively new in the field of spinal surgery. A TFR implantation involves the complete removal of bilateral facet joints (facetectomy) and prosthetic replacement, to be distinguished from lumbar posterior dynamic stabilization devices (to be discussed in a separate chapter) that preserve the in situ facet joints and augment the motion of the FSU through a flexible motion-preserving design.

The TFR procedure is proposed as an alternative to posterior spinal fusion in patients with degenerative spinal conditions. As an emerging technology, the indications and available devices are evolving at present. Potential future applications of a TFR system may include (1) complete 360° arthroplasty of the motion segment (concomitant TDR and TFR) that will entail complex biomechanical and wear related considerations and (2) TFR systems for patients in which facet joint arthropathy (Fig. 93.1) requires a wide decompression (facetectomy) for adequate decompression of the neural elements. The current generation of TFR devices and clinical trials has been designed for the latter indication.

The facet joints bear approximately 15% of the physiologic axial load of the spine in the standing position with

Fig. 93.1: Computed tomography images of facet joint arthropathy on coronal view. Arrows point to facet joint arthritis.

the remainder transmitted through the anterior column and the intervertebral disk. The proportion of load transmitted through the facet joint increases in extension and as the degeneration of the motion segment progresses.^{1,2} Isolation of the “pain generator” in degenerative conditions causing low back pain remains challenging, as does the diagnosis of patients with “facetogenic” pain. Computed tomography assessment is better suited to diagnose facet arthropathy;³ however, radiographic facet degeneration may be seen in more than half of asymptomatic patients,⁴ which highlights the diagnostic conundrum. Not surprisingly, despite encouraging cadaveric biomechanical

Fig. 93.2: Drawing of posterolateral view of the ACADIA facet replacement system device.

Fig. 93.3: Lateral plain radiographic view of the ACADIA facet replacement system device.

data and theoretical underpinnings, the clinical results of facet arthroplasty have been mixed. As such, the current generation of TFR implants with its varied material composition and design strategy will likely undergo multiple iterations of modifications as a broader clinical experience accumulates. The following discussion will focus on the design features and current clinical data on TFR devices.

TOTAL FACET REPLACEMENT DEVICES

ACADIA Facet Replacement System

The acadia/anatomic facet replacement system (AFRS) implant (Facet Solutions, Inc., Hopkinton, MA, acquired by Globus Medical, Audubon, PA, in January 2011) is a pedicle screw-based design that is composed of superior and inferior facet implants (Fig. 93.2). The cobalt-chromium-molybdenum articulating facet surfaces are linked by a crossbar that spans the inferior facet implants from left to right.

The AFRS is being evaluated as part of a phase III Food and Drug Administration (FDA) investigational device exemption (IDE) clinical trial that is currently recruiting with an estimated enrollment of 300 patients. Patients were randomized 2:1 either to the investigational ACADIA device (Fig. 93.3) or to instrumented posterolateral fusion (PLF). Several of the inclusion criteria are patients with lateral, lateral recess and/or central stenosis, who failed >6 months of nonoperative management, and who are the candidates for a full facetectomy for decompression with preservation of disc height (measuring ≥ 4 mm). Patients with prior lumbar spinal surgery, spondylolisthesis >grade I,

and retrolisthesis were excluded. Primary outcome measures are improvement in Zurich Claudication Questionnaire Physical Function, and Symptom Severity scores, lack of device-related serious events, maintenance or improvement of neurological status, and no device failures requiring revision, removal, reoperation, or supplemental fixation.⁵ Final data collection was scheduled for October 2013.

In 2012 early results of the ACADIA IDE study were reported. These preliminary data indicated that improvements were seen in all function and pain outcome measures at 12 months postoperatively and high levels of patient satisfaction for both the study group and the PLF control group.⁶ The 100th patient in the IDE study was enrolled in 2012 and peer-reviewed publication and longer follow-up of these cohorts are pending at the time of writing of this chapter.

Total Facet Arthroplasty System

The total facet arthroplasty system (TFAS) implant (Archus Orthopedics, Inc., Redmond, WA, acquired by Facet Solutions, Inc., Hopkinton, MA, in 2009, acquired by Globus Medical, Audubon, PA, in 2011) is a nonfusion spinal implant composed of a metal-on-metal articulation with two cephalad bearings that articulate with two caudal housings (Figs. 93.4A and B). The caudal housings are linked by a cross-arm assembly that is anchored to the cephalad components by a medial locking mechanism. The caudal housings permit flexion and extension as the spherical components translate throughout the base of the housing in the metal-on-metal articulation.

Figs. 93.4A and B: Drawing of lateral view (A) and posterior view (B) of the total facet arthroplasty system device.

Fig. 93.5: Anterior-posterior (left) and lateral (right) plain radiographs of the total facet arthroplasty system device in vivo.

The implant was designed to replace the diseased facets in patients with severe spinal stenosis that would require a wide decompression involving complete removal of the facet joints (Fig. 93.5). Purported advantages were a more normal physiologic motion profile at the operative and adjacent segment and the avoidance of donor-site iliac crest autograft morbidity that may be required for posterolateral fusion.

The TFAS device to date is the most studied TFR implant in the peer-reviewed literature in preclinical biomechanical studies. Cadaveric flexibility tests were reported on an intact and an injury model after stabilization with the TFAS and posterior pedicle screw systems at L4–L5 in 2007. Range of motion (ROM) with the TFAS was less than the intact specimen in all planes of motion (81% in flexion,

68% in extension, and 88% in lateral bending) except for an increase ROM in rotation (128% axial rotation).⁷ Following complete decompression (laminectomy and facetectomy) at L3–L4, TFAS was reported to restore near-normal motion at the adjacent motion segments.⁸ Reproduction of intact-like anterior column load-sharing as measured by disc pressure was reported in a cadaveric model; however, there were differences in implant moments between TFAS and a standard pedicle screw implant system.⁹

The phase III FDA IDE study of the TFAS device started in 2005 with an estimated enrollment of 450 patients with persistent leg symptoms, including pain, numbness, burning, or tingling for a minimum of 6 months with no more than three levels of degenerative lumbar stenosis requiring decompression. The study was later discontinued for reported financial reasons in 2011.^{10,11} Preliminary data from the TFAS IDE study in 2012 reported on 59 patients who underwent TFAS procedure and were instrumented at either L3–L4 or L4–L5. A statistically significant decrease in flexion-extension motion that was observed at the operative level between preoperative and postoperative radiographs at 12 months, however, was restored to near-normal ROM at the 24-month time point. Both the cranial and caudal adjacent levels demonstrated similar motion to preoperative at both the 12- and 24-month time points.¹² A report emerged of two patients from the IDE study with stem fracture of the TFAS implant at 9 months and 27 months postoperatively. Both patients were implanted with TFAS at the index surgery for an indication of L4–L5 spondylolisthesis with stenosis. The authors suggested that the biomechanical mechanism of TFAS breakage might be similar to pedicle screw breakage in the setting of

Figs. 93.6A and B: The total posterior facet replacement system is designed with two titanium plates and an outer polycarbonate urethane capsule. The capsule contains an articulating PcU component that is intended to duplicate the function of the facet joints. *Source:* Reproduced with permission, Elsevier Ltd, Oxford, UK.

pseudarthrosis indicating fatigue failure and three-point bending stresses. Both patients were revised with transposas lateral lumbar interbody fusion uneventfully.

Total Posterior Facet Replacement

The total posterior facet replacement (TOPS) implant (Impliant Ltd., Ramat Poleg, Israel, acquired by Premia Spine, Ltd, Herzela, Israel) is a pedicle screw-based facet arthroplasty system consisting of metal and plastic components. A polyurethane articulating construct allows motion between two titanium plates that are secured to the motion segment by four hydroxyapatite-coated polyaxial pedicle screws. The crossbars are joined together by an elastic component that is designed to transmit loads between the components (Figs. 93.6A and B).

Biomechanical studies of the TOPS device in human cadaveric specimens at L4–L5 demonstrated 85% of the intact specimen ROM was restored in the sagittal plane and near-complete restoration of motion in lateral bending and axial rotation.¹³ A subsequent report described ROM values with the TOPS System that were not significantly different from the intact values.¹⁴ Cadaveric evaluation of intervertebral disc bulging and anular fiber strains with the TOPS device was associated with a slight decrease in fiber strain (5%) compared to intact specimens in flexion, but maximum fiber strains doubled from intact (6.5–13.8%) in lateral bending.¹⁵ Both were considered to be within the physiologic range by the authors.

Preliminary clinical data of 29 patients undergoing tops from the nonrandomized multicenter (uncontrolled) pilot

study was reported with mean surgical time of 3.1 hours for a single-level procedure (L3–L4 or L4–L5 TOPS implant following complete bilateral total facetectomy and laminectomy).¹⁶ Oswestry Disability Index decreased compared to baseline by 41% at 1 year and the VAS score declined 76 mm with reported radiographic analysis that showed restoration of lumbar motion, preservation of disc height, and no evidence of implant loosening. Longer outcomes have not been reported to date.

The FDA prospective randomized controlled IDE study started in May 2008 and was designed to enroll an estimated 450 patients aged 40–75 years with VAS leg pain of at least 40/100 at baseline and Oswestry Questionnaire score of at least 40/100 at baseline.¹⁷ The study was temporarily suspended in 2008 voluntarily by the manufacturer after a report of a device-related failure due to the inability of the components to sustain the in vivo shear loads.¹⁸ Reportedly a design modification was made at that time to better withstand these loads. Peer-reviewed publication of the TOPS IDE trial has not been reported to date and the device is not currently commercially available in the United States.

CONCLUSION

The physiologic demands on a facet arthroplasty device far exceed those of a rigid fixation fusion construct. While pedicle screw instrumentation of a motion segment is required to withstand implant moments and loading conditions until fusion has occurred, a TFR implant must withstand these forces indefinitely. Some authors have suggested that indications for this technology in a “stand-alone” fashion

may be limited given that the intervertebral disc is left in situ and represents a potential nociceptive source. Preservation of motion with an instrumented pedicle screw-based system holds theoretical concern for three-point bending stresses on the “stem” of the implant and subsequent fatigue failure over the hundreds of thousands of in vivo motion cycles that the implant must tolerate. Indeed, fatigue failure of the implant resulting in stem fracture was reported with the TFAS implant. Little is known at present about the in vivo wear patterns of the current TFR implant designs and the associated long-term clinical sequelae. To date, there is no facet arthroplasty device that has been approved by the FDA, yet intrigue for the potential to completely replace the facet joints alone, or in combination with the entire three-joint complex of the FSU, remains high.

KEY POINTS

- Total facet replacement is considered investigational at the present time. There are currently no FDA-approved TFR devices.
- Biomechanical in vitro data suggest near-normal duplication of the operative and adjacent motion segments with TFR devices is feasible.
- Implant failure remains a theoretical concern for pedicle-based facet arthroplasty systems. Case reports have emerged of stem fracture of TFR designs.
- The ideal TFR device will re-create normal physiologic range of motion at the operative and adjacent motion segments with minimal wear and will be able to withstand the bending moments and loading conditions of the spinal motion cycle without undergoing fatigue failure.
- Future applications of TFR may include 360° replacement of the spinal motion segment—simultaneous TDR and TFR.

INTRODUCTION

The modern era of lumbar arthroplasty began in East Berlin in the early 1980s, with the development of the SB Charité disc (later manufactured by LINK; Hamburg, Germany) by Karin Büttner-Janz and Kurt Schellnack.^{1,2} Through several iterations, it was first implanted in patients in Europe in the mid-1980s with mixed results. Patient selection and technical issues with access and implantation (mobilization and placement) led to some poor clinical results. The intrinsic unconstrained design of the Charité implant was philosophically appealing, but the dramatic in vitro demonstrations of its ability to move the center of rotation did not translate into favorable in vivo results when it was implanted into a surgically destabilized segment.

Despite the negative 1990s response to lumbar arthroplasty outside the United States, a Food and Drug Administration (FDA) investigational device exemption (IDE) trial of Charité controlled by comparison to anterior lumbar interbody fusion (ALIF) with stand-alone paired BAK cages (Zimmer Spine, Austin, TX) started in 2000.³ This was the first premarket approval (PMA) arthroplasty study in the United States. The Charité study was initiated by Link and the arthroplasty technology was ultimately acquired by DePuy-Johnson & Johnson.

Also in the late 1980s and early 1990s, Thierry Marnay, a French orthopedic surgeon, was working on the

development of the ProDisc implant. Based in southern France and on the western side of the Iron Curtain, he was only marginally aware of the work at the Charité Hospital in East Germany. Marnay's design was a keeled, semiconstrained implant, and he and a colleague implanted 93 devices in 64 patients between 1990 and 1993. They then had the academic restraint to stop implanting and to clinically follow those patients. In the late 1990s, a US company (Spine Solutions, Inc., New York) independently reviewed radiographs, interviewed Marnay's patients, and used that data to convince the FDA to allow them to start a multicenter trial in the United States comparing ProDisc to a 360° (combined anterior and posterior) spinal fusion. Both one- and two-level study arms were initiated. The first surgery of the single-level arm occurred in October 2001, and the first two-level surgery in the United States was performed in January 2002, both at the Texas Back Institute.

Other lumbar devices have subsequently pursued the PMA track with prospective randomized multicenter trials, including the Maverick (Medtronic, Memphis, TN) not commercially available in the United States, the Flexicore (IDE withdrawn by Stryker Spine, Allendale, NJ), the Kineflex-L (SpinalMotion, Mountain View, CA), the Active-L (Aesculap, Center Valley, PA), and the Freedom (Axiomed, Garfield Heights, OH) devices, all in FDA queue in final data collection. The Kineflex study was the first to randomize to another total disc replacement (TDR) (Charité).

Active-L randomized to either Charité or ProDisc, and Freedom randomized to ProDisc. As of this date, only Charité and single-level ProDisc-L have achieved FDA approval in the United States. With the worldwide withdrawal of Charité in 2011, only ProDisc-L is currently commercially available for implantation in the United States. The Charité withdrawal from the market was primarily due to a business decision occurring around the time Depuy acquired the ProDisc through its merger with Synthes.

Two-year multicenter IDE data has been published for Charité, ProDisc, and Maverick.³⁻⁵ Five-year multicenter outcomes data has been published for Charité and ProDisc-L.⁶⁻⁸ In a prospective, randomized fashion, arthroplasty patients demonstrated improved outcomes using standard measurement instruments such as the Oswestry Disability Index (ODI) and visual analog scale (VAS) assessing pain compared to the fusion cohorts at 2 years for all three devices.³⁻⁵ At 5 years, both the Charité and ProDisc clinical results were maintained at similar levels to the 24 month data.^{6,8} Reoperation rates at both index and adjacent levels were lower in the arthroplasty patients as well.

Most recently, Zigler et al.⁹ have shown that radiographic degeneration at the adjacent level is statistically significantly reduced at 5 years when comparing patients randomized to ProDisc-L versus 360° fusion. The multiparameter adjacent level changes, graded by independent radiologists, were three times greater in the fusion group.

Despite very strong clinical and radiographic data showing benefits with arthroplasty, adoption of this technology has been slow. A significant impediment has been reluctance on the part of major insurance carriers to authorize payment for this technology, continuing to consider it “investigational and experimental” despite FDA approval in 2004 and 2006 for Charité and ProDisc, respectively. Another impediment to adoption is the need for an access surgeon to provide safe and consistent anterior exposure of the lower lumbar spine, since few spine surgeons choose to do their own approaches. A final challenge to more widespread adoption has been the relatively poor reimbursement for lumbar arthroplasty, even by those companies that have approval for its use. Reimbursement to the surgeon is approximately half that for a segmental fusion.

Several economic studies have shown that both direct and indirect costs are reduced with arthroplasty.¹⁰⁻¹³ Return to work, return to recreational activity, and post-operative pain medication use are all more favorable in the arthroplasty patient cohorts.

The scientific evidence in the published literature regarding the benefits of both arthroplasty and fusion is

very strong, thanks to these multicenter IDE studies. We now know more about the advantages of both lumbar fusion surgery and disc arthroplasty over nonoperative care for the treatment of functionally disabling degenerative disc disease of the lumbar spine. Historians will likely look upon the slow adoption of this technology with bewilderment, as the databases grow more robust with age, and the results are so strongly maintained in the literature.

BIOMECHANICAL CONSIDERATIONS

The spine has both a functional and protective role. First and foremost, the osseous anatomy of the spine functions to protect the thecal sac and neural structures. Simultaneously, the spine allows for coordinated motion in space. The forces acting on the spine (compressive, shear, tensile and torsional) are, under normal physiologic conditions, absorbed by anatomic restraints. White and Panjabi¹⁴ first described the functional spinal unit (FSU) or the spinal motion segment, which includes the adjacent vertebral bodies, the intervertebral disc and the two facet joints. The FSU also includes stabilizing ligaments but does not include muscles. The FSUs have been used extensively to study biomechanical properties of the spine. Load-displacement of the FSU is nonlinear, with two distinct regions—neutral zone and the elastic zone. These two zones exhibit differing biomechanical properties (Fig. 94.1). The neutral zone shows minimal internal

Fig. 94.1: A spinal segment is very flexible at low loads associated with the neutral zone and stiffens with greater load noted in the elastic zone. The load deformation relationship is a sharp curve, rather than linear.

resistance during passive motion, where a small load produces a large displacement in space. From the end of the neutral zone to maximum resistance (the extent of motion allowed by the stabilizing structures) represents the elastic zone.^{15,16} The goal of the “perfect” TDR device is to reassimilate, as best possible, the normal segment motion and forces after removal of the anterior longitudinal ligament and the diseased intervertebral disc.

One of the most debated design fundamentals for artificial disc replacement is the concept of constraint. With the ProDisc-L, motion of the operative segment is limited by a ball-and-socket articulation design (semiconstrained device), whereas the mobile core design of the Charité disc (unconstrained device) imparts less restriction on motion (Figs. 94.2A and B). The mobile core translates freely within the device, thereby having motion that closely assimilates that of the normal spine. It was postulated that this design reduces stress imparted to the polyethylene core. The constrained device has 5 degrees of freedom (DOFs), whereas the semiconstrained device has 3 DOFs. These parameters potentially can have a profound effect on transmission of forces to the facet joints, vertebral endplates and possibly the adjacent intervertebral disc as well. Most lumbar TDR devices currently in FDA IDE trials employ some type of constraint.

Unfortunately, the biomechanical literature is confusing and often contradictory, making it difficult to draw steadfast conclusions about constraint. In theory, unconstrained devices are thought to have less stress imparted to the facet joints because they allow for motion resembling more normal motion. Rousseau et al.¹⁷ showed in a cadaveric

model that the degree of constraint of the implant does in fact affect load transfers and kinematics of the arthroplasty device, with the Charité implant having significantly less variation in the position of the instant axes of rotation (IAR). But in contrast to the general theory, this study showed that the forces imparted to the facet joints after implantation of an unconstrained device were found to increase significantly in all motions, especially in lateral bending. The more “physiologic” mapping of segmental motion with the unconstrained device has also been shown in other cadaveric studies in which the IAR resides in the posterior one-third of the disc space, as is found with intact segments.¹⁸ With the ProDisc device, the facet joints were found to be unloaded throughout flexion and extension.¹⁷ Interestingly a study assessing the IAR of fixed center semiconstrained devices found this design to impart more stress to the vertebral endplate due to incongruent surfaces. Finite element models have also been used to show the unconstrained devices impart less stress to the vertebral body and endplate, as well as lessen facet contact forces.¹⁹ In direct opposition, other finite element models have predicted increased facet joint forces using the unconstrained versus the constrained implants.²⁰ More long-term in vitro and in vivo mechanical analyses will be needed to determine which (if either) design is superior.

In regard to transmission of forces to the adjacent disc, many cadaveric investigations have shown both constrained and unconstrained total disc designs maintain or reduce the adjacent level disc pressures compared to fusion.^{18,21-24} How this correlates clinically is yet to be fully determined. The only level 1 evidence currently available

from the ProDisc IDE study shows radiographically at 5 years there is statistically less adjacent level degeneration with arthroplasty as compared to fusion.⁹ Other factors may play a significant role in adjacent segment degeneration (ASD), including the age of the patient at the time of implantation and genetic predisposition of the patient to develop advanced degeneration changes throughout the spine.

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

The ideal patient for lumbar arthroplasty is likely to be their 40s or 50s and has functionally disabling single-level lumbar disc disease at L3-L4 through L5-S1. The patient has failed at least 6 months of nonoperative care, has a pain VAS of $>7/10$, and has a bone density with a T-score of > -1.0 . From the published clinical trials, TDR was associated with early and significant improvement in both ODI and pain VAS, which was maintained during the 5 years follow-up.^{3,4,6,8} The typical patient has predominant low back pain. Patients frequently have pseudo-radicular leg pain (radiating to the buttocks and hamstring, but not below the knee). Patients who have disc space collapse after previous herniated nucleus pulposus (HNP), with or without prior surgical treatment, may have concomitant true radicular pain from vertical collapse of the foramen; however, these patients can still be considered for arthroplasty. The subset of ProDisc IDE patients with post-HNP disc space collapse (approximately one-third of the IDE population) actually had better outcomes than average.⁴ Even very collapsed discs can be mobilized, although more technically demanding, even in experienced surgical hands, as long as the facets are not excessively arthritic. Functional outcomes were not found to be related to preoperative disc height.

The most typical symptoms in the ideal patient are transverse lumbosacral pain associated with prolonged sitting or standing. These patients will typically give a history of constant fidgeting in their seats, or of constant shifting from one leg to the other when forced to stand in one place. They prefer to keep moving and have less pain with walking than standing. The question "Can you sit comfortably through a movie?" is a very effective screening tool.

Physical examination findings are generally minimal, except for transverse lumbosacral tenderness, and occasionally paralumbar muscle spasm. Neurologic signs are typically absent. Straight leg raise is usually normal, except for hamstring tightness. Patients who have exquisite

Fig. 94.3: Lateral radiograph showing significant intervertebral collapse at the L5-S1 level with retrolisthesis of L5 on S1 and vacuum phenomenon within the disc space.

pain on extension may respond to facet blocks but generally are not improved beyond a short period of time.

Radiographic findings may include decreased disc height. Collapse with retrolisthesis of the cephalad vertebral body may be seen in more advanced cases (Fig. 94.3). True dynamic instability according to White and Panjabi's criteria¹⁴ is rare in purely degenerative cases, but significant retrolisthesis is indicative of failure of segmental stability. A vacuum phenomenon in a collapsed disc is a fairly reliable sign on plain radiographs that the degenerative segment can be mobilized at the time of anterior discectomy.

The magnetic resonance imaging (MRI) findings may vary from simple decreased signal on T2 sagittal images to protrusions, annular bulges and herniations to frank collapse with Modic changes on one or both endplates. One of the best uses of MRI is to evaluate the integrity and hydration of the adjacent lumbar discs in comparison to the degenerative disc or previously operated disc (Fig. 94.4). Pristine signal at all other levels with only a single collapsed disc space (with or without previous surgery) is a relatively straightforward diagnosis in a patient with disabling back pain who has failed conservative care.

A more difficult diagnostic scenario occurs when patients have typical symptoms, a negative neurologic examination, and have multiple discs with abnormal signal and varying degrees of degeneration. With the knowledge that 40% or more of the asymptomatic population may have abnormal disc signal on MRI,^{25,26} surgeons must identify the pain generator, which often requires further

Fig. 94.4: Sagittal T2-weighted magnetic resonance imaging showing a single-level degenerative disc with normal appearing discs otherwise. Patient had a positive discogram for concordant pain with morphological changes at the L4-L5 level. This patient is an excellent candidate for total disc replacement.

Fig. 94.5: Sagittal T1-weighted magnetic resonance imaging showing multiple degenerative levels of varying severity. This patient is not a candidate for surgical reconstruction.

investigation. Although the use of discography remains controversial in some regions, most surgeons who frequently operate on axial back pain feel that discography is an indispensable tool that should be used in the diagnostic algorithm. In the scenario of multiple degenerative discs at varying stages, discography can be the vital part of the equation, and often serves to guide therapeutic decision making.

An older patient with two-level disease on imaging, both causing significant concordant pain reproduction on discography, should not be offered a single-level reconstructive option with an expectation that surgery will be successful. Similarly, a younger patient with three or four anatomically abnormal and significantly painful lumbar discs is not a candidate for surgical reconstruction (Fig. 94.5). Three- and four-level operations on young patients will undoubtedly create long-term problems while they are still in their productive working years. These younger patients with multilevel disease should be advised to consider pain management options while technology and biologic research are advanced, with the hope of better treatment options for them in the future, rather than proceeding with bridge-burning procedures now.

Off-label uses of arthroplasty technology (multiple levels, hybrid constructs) are generally not approved by insurance carriers, so that clinical experience in the United States is limited to scattered small case series. Good clinical outcomes have been reported in the two-level

ProDisc-L IDE study;²⁷ however, the approval of two-level arthroplasty by the FDA has yet to be attained. Hybrid constructs have not been studied in any prospective level I studies to date.

One of the most exciting benefits of the IDE study data concerns the protective effect of arthroplasty on the adjacent level.⁹ Radiographic changes of decreased disc height, endplate sclerosis, osteophyte formation, and spondylolisthesis were found adjacent to single-level fusions three times more frequently than adjacent to arthroplasty implants at 5 years follow-up. These two patient cohorts were enrolled in the ProDisc-L versus 360° fusion FDA IDE study, and these comparisons were made between preoperative and 5-year postoperative radiographs. Assessments were done by independent radiologists, and the findings were highly statistically significant. This points to a clear advantage of arthroplasty in the treatment of single-level disc disease, and longer follow-up may correlate these radiographic findings with a decrease in the need for adjacent level surgery in the arthroplasty group.

Contraindications for disc arthroplasty have also been set forth by the IDE studies. As mentioned before, bone density is a necessary preoperative investigation. A T-score of < -1.0 is a contraindication to TDR. The presence of significant spondylolisthesis greater than grade I is also an absolute contraindication. Scoliotic curves $>11^\circ$ should not be offered a disc replacement at any level. The presence of current or past infection at the operative level, tumor, significant facet arthritic changes, excessive facet

removal from previous surgery and significant metal allergy are all impediments for arthroplasty. Any relative or absolute contraindication for anterior exposure of the lumbar spine for fusion should also be considered in deciding whether patients are arthroplasty candidates, including multiply operated upon abdomen, previous retroperitoneal approach, history of serious pelvic inflammatory disease, and significant atherosclerotic vessel disease in the abdominal vessels.

SURGICAL TECHNIQUE

The operating room setup maximizes the efficiency of the procedure. Use of a large operating room is recommended to accommodate personnel and equipment. The patient should be supine on the radiolucent operating room table positioned so that the base of the table does not interfere with the C-arm. Positioning of the access surgeon and primary surgeon is based on personal preference. The “French position” (surgeon between the patient’s abducted legs) technique is an alternative technique. The top of the iliac crest should be positioned in line with the “break” in the table, in order to hyperextend the lumbar region for better intraoperative visualization of the disc space. The plane of the pelvis is based on the position of the anterior superior iliac spines, and should be parallel to the floor. The arms should be padded and wrapped in front of the patient’s chest and out of the fluoroscopic field. The lower extremities should be in neutral position, with appropriate padding.

A paramedian, left-sided incision is preferred for the retroperitoneal approach. A right-sided approach for L5-S1 can be used in cases when the patient has lesser degree degenerative discs at L4-L5 or L3-L4, so the left retroperitoneal approach remains viable for a subsequent procedure. Following a retroperitoneal approach, retrograde ejaculation occurrence has been shown to be 10-fold less than after a transperitoneal approach.²⁸ Laparoscopic techniques have failed to prove beneficial.

The incision can be made vertical or horizontal for a one-level procedure, depending on the size of the patient. Usually a 6–8 cm paramedian, horizontal incision is used at the level of the disc space to be approached. In the case of larger patients, the vertical incision should be used to allow for a more extensile exposure (Fig. 94.6). Based on the relation of the L4-L5 disc space to the iliac crest on preoperative lateral radiographs, the incision should be situated caudal or cephalad on the abdomen to the level

Fig. 94.6: Illustration showing potential abdominal incisions for the retroperitoneal approach to the different levels of the lumbar spine.

Fig. 94.7: Cross-sectional view showing the plane of dissection for the retroperitoneal approach to the lumbar spine.

of the iliac crest. The angle of the intended disc space can also be verified with a lateral fluoroscopic image.

Following the skin incision, bovie cauterization is used to dissect down to the anterior rectus fascia. The fascia is incised obliquely and the midline fascial raphe of the rectus should be identified. The left rectus is then mobilized to the left with careful attention to avoid injury to the inferior epigastric vessels. Blunt dissection is used to develop the plane superficial to the peritoneum. The plane is dissected on the left abdominal wall around the sigmoid colon and posterior toward the psoas muscle (Fig. 94.7). The entire peritoneum can be bluntly dissected and separated from

the abdominal wall. The ureter should be visualized to remain attached to the posterior peritoneum. Handheld retractors are used to retract the peritoneal contents from left to right. For L5-S1 approaches, the middle sacral artery (or arteries) must be dissected and ligated in the space between the common iliac veins overlying the disc space. For L4-L5 approaches, the ileolumbar vein (or veins) frequently tethers the iliac vein and can inhibit proper mobilization of the great vessels. If so, this vein must be identified prior to mobilization of the great vessels and ligated. Also, segmental arteries should be identified. They are rarely ligated for L4-L5 and L3-L4 single-level approaches.

Once the peritoneum has been successfully mobilized and the vascular structures protected, the intended disc space(s) must be verified with fluoroscopic imaging. Often there is inflammatory tissue anterior to the spine, making dissection and mobilization of the vascular structures tedious and more difficult. Either table-held retractors or handheld vein retractors can be used on each side of the spine to create a safe working environment.

Confirmation of the desired level and identification of midline are crucial. A bent spinal needle, a specialized marker, or a large-fragment screw can be used and placed into the disc space in the anticipated midline. Lateral fluoroscopic images are used to verify the disc level. With the spine in neutral rotation, an anteroposterior (AP) image is used to show the relation of the marker to the true midline. Landmarks such as the symmetry of the pedicles, the position of the vertebral body margins, and the midline position of the spinous process are used to verify midline. Cautery is then used to mark the midline on the adjacent anterior vertebral body or the placement of a specialized marker can also be used.

An anterior anulotomy centered on the midline mark is then completed using a long-handled knife, cutting away from retracted vessels. A Cobb elevator is then used to carefully dissect the plane between the disc material and the endplates. The majority of the disc can then be excised using a pituitary rongeur. With severely collapsed disc spaces, curettes are used to dissect into the disc space. Larger curettes are used to remove the cartilaginous endplate. Perforation of the endplate should be absolutely avoided in arthroplasty cases. The entire disc space should be cleaned of disc material and cartilage, leaving behind both lateral anulus and the posterior longitudinal ligament. For arthroplasty cases, meticulous discectomy in the posterolateral corners is also crucial for successful remobiliza-

Fig. 94.8: Intraoperative picture showing a symmetric, completed discectomy

tion of the segment. The final discectomy should be symmetric (Fig. 94.8).

Restoration of the disc height is crucial in order to allow for a mobile segment. Often the disc space is significantly degenerative and collapsed, making it necessary to release constraining soft tissues. An angled curette within the disc space can be used to dissect the posterior longitudinal ligament (PLL) away from the vertebral bodies, which makes remobilization easier. Lateral fluoroscopic images should be utilized with the curette in place to aid in PLL dissection. In some cases, there is a posterior ledge of bone that may need to be removed in order to get the prosthesis posterior as possible. A curette or a Kerrison rongeur is often needed. In very collapsed disc spaces, the PLL may need complete resection to successfully mobilize the segment. Specialized distractors also aid in remobilization of the segment. Care must be taken to insert the distractors posterior in the disc space resting on the peripheral cortical ring, to avoid perforation of an endplate (Fig. 94.9).

Once remobilization of the disc space is completed, trial implants can be inserted into the disc space. For the Synthes ProDisc-L, a 10 mm trial is used at first, and increases in size are dependent upon the resistance encountered and the comparison to the relative disc height of the adjacent levels, as seen on the lateral fluoroscopic images. The trials should be centered on the previously made midline mark. Once the appropriate trial is placed, an AP image is taken to verify the position of the trial in relation to the midline. If the trial is translated off-center, further soft tissue releases or discectomy may be required to “balance” the disc space, allowing the trial to center.

Fig. 94.9: Intraoperative lateral fluoroscopic image showing disc space distractor in correct position and curette dissection of posterior longitudinal ligament off the posterior vertebral body.

Fig. 94.10: Intraoperative lateral fluoroscopic image showing the correct position of the ProDisc-L implant at L4-L5 in relation to the posterior vertebral bodies.

Table 94.1: The varying sizes of available ProDisc-L implants.

Endplate footprint	Medium 34.5 × 27 (mm)	Large 39 × 30 mm
Superior endplate angulation	6°	11°
Polyethylene inlay thickness	10 mm, 12 mm, 14 mm	

At the time of this writing, the only FDA-approved device in the US market in the lumbar spine is the ProDisc-L. The size of the implant should be decided from the tactile feedback and fit of the trial component. There are several variations and combinations in width, depth and height for the ProDisc-L device (Table 94.1). The ProDisc-L device is a keeled device and therefore also requires preparation of the vertebral bodies for the keels. This is completed by using the appropriately sized chisel that is placed over the trial insertion stem and the chisel is impacted into the vertebral body under lateral fluoroscopic imaging. If the table has been hyperextended for disc space preparation, the angle should be returned to neutral before cutting the keel. After keel preparation, the disc space should be debrided of any remaining disc or cartilaginous debris.

The prosthesis can now be inserted along the keel tracts. Using steady, deliberate mallet blows, the prosthesis is inserted into the disc space along the keel tract under lateral fluoroscopic imaging. Lateral fluoroscopic images are used to verify the trajectory angle as well as the depth of the implant. Ideally, the device should be inserted as far posterior as possible into the disc space (Fig. 94.10). The

Fig. 94.11: Intraoperative anteroposterior fluoroscopic image showing correct position of the ProDisc-L implant at L4-L5. Note the relationship of the keels to the spinous processes and the symmetric position of the prosthesis in relation to the pedicles and the lateral vertebral body.

ProDisc-L polyethylene portion of the bearing surface is inserted last, between the two endplates. Proper insertion and locking of the polyethylene component must be verified. A final AP image should be taken to verify position of the prosthesis to be within the center of the disc space, using the anatomic landmarks mentioned before (Fig. 94.11). If the implant is off-center by a significant distance, the device may need repositioning and the keels

cut again. Finally, gross inspection of the implant and disc space should be done to verify there is no significant debris between the bearing surfaces and to verify proper assembly.

COMPLICATIONS

As with all spinal surgery, successful outcomes are dependent upon avoiding complications. Arthroplasty complications can be divided into three main categories: approach-related complications, technical complications and device-related complications.

Approach-Related Complications

The anterior retroperitoneal approach to the lumbar spine by a skilled access surgeon should be a minimally invasive technique. Through careful exposure and adequate retraction, complications can be minimized. Approach-related complications are similar for TDR and anterior fusion procedures. The most common complication encountered in anterior exposures is vascular injury—predominantly to the venous structures and very rarely an arterial injury. These injuries can be catastrophic without the experienced surgeon on hand for vascular repair. Direct injury or clot is found to occur <1% of cases.²⁹ Although some spinal surgeons are certainly adept at exposure of the anterior lumbar spine, a multidisciplinary approach using an access surgeon can be beneficial to address any approach-related complications that may occur.

With the advent of the less invasive retroperitoneal technique for exposure, retrograde ejaculation has been minimized from 13.3% (with the transperitoneal approach) to 1.7%.³⁰ Careful dissection of the hypogastric plexus up and off the vessels prior to retraction can aid in avoidance of this complication.

In the ProDisc IDE study at 5-year follow-up, the number of adverse events between the TDR group and the fusion group was not significantly different, including retrograde ejaculation.⁸ Severe, life-threatening events were found to occur significantly more often in the fusion group. No infections were reported in the TDR group, whereas the fusion group had two posterior wound infections. All deaths in the study were found to be unrelated to the surgical intervention. Other potential approach complications include ileus, thrombophlebitis, incisional hernia, warm feeling leg, nerve palsy, ureter injury, and bowel injury.

Technical Complications

Improper midline identification is the most common technical complication that can occur. During fluoroscopic verification of the midline, the surgeon must make a visible mark in the vertebral body or use a radio-opaque marker to aid in the remainder of the surgery. For accurate determination of midline, use of the lateral margin of the vertebral body as a reference is more reliable than using the spinous processes.³¹ Accurate midline identification is especially important with keeled prostheses because repositioning is much more difficult after an improper keel track has been cut into the vertebral body. Throughout the procedure, the surgeon should carefully perform discotomy symmetrically about the midline mark. If an un-keeled prosthesis is malpositioned in relation to the midline, removal, and repositioning are a must; however, keeled prostheses present a challenge for the surgeon because cutting a second keel introduces a significant risk of fracture between the two keels and creating a loose implant. There is no definitive study with recommendations about what is an acceptable intraoperative position. The goal should be to have the midline of the prosthesis to be within 3 mm of the vertebral midline on final AP fluoroscopic image. If the implant is too far off the midline, asymmetric loading of the endplate and facet joints can occur, which could lead to postoperative pain source.

Anterior-posterior placement of the device is also important for successful outcomes. In order to best recreate normal spinal segment motion, the prosthesis should be positioned as far posterior within the disc space as possible based on lateral fluoroscopic images. A posterior-placed device allows a more physiologic transfer of loads to the vertebral bodies and aids in unloading facet joints during lumbar extension.³² For the unconstrained device, the center of rotation more closely mimics that of the normal spinal segment, whereas in the constrained devices the center of rotation lies slightly anterior to that of physiologic motion.³³

Proper endplate preparation is paramount for avoiding complications. Improper trajectory with a curette or other instrument during endplate removal can lead to weakening of the support structure for the implant and possibly future subsidence and/or fracture of the endplate. If recognized intraoperatively, conversion to anterior fusion should be considered if the endplate violation is sizable.

Intraoperative fracture can occur, especially fracture of the posterior vertebral bony edge on the cephalic vertebral body. Usually, this is a result of inadequate posterior release of the anulus and posterior longitudinal ligament.

Sometimes the posterior bony edge needs to be removed in order to obtain a better position of the prosthesis and also to avoid fracturing the posterior vertebral lip during trialing or implant insertion.

Subsidence can also be caused by undersizing the prosthesis, where the edge of the prosthesis rests on the concave portion of the vertebral body instead of the strong apophyseal ring. Conversely, oversizing the implant may result in dislocation of the device.

Preoperatively unrecognized osteopenia or osteoporosis can place all prostheses at risk for early postoperative subsidence and failure, regardless of size and position. Preoperative bone density scans aid in proper patient selection, even in male patients. A T-score of > -1.0 is required for arthroplasty patients.

Device-Related Complications

Longevity of artificial disc replacements may be threatened by intrinsic factors, such as wear debris and its consequences. Through retrieval studies, it has been shown that both unconstrained and constrained implants have characteristic patterns of wear. With the unconstrained design, adhesive and abrasive wear occurred in the domed portion of the polyethylene core as well as chronic rim impingement, resulting in fracture of the core in some patients.^{34,35} The constrained devices show posterior burnishing/impingement of the metal endplates, backside wear of the polyethylene and evidence of third-body wear.³⁶ Once wear debris accumulates about a prosthesis, the long-term effects on the adjacent osseous anatomy may potentially lead to osteolysis and subsequent implant subsidence. The osteolysis is theorized to be caused by particle-induced activation and exhaustion of macrophages. This creates a proinflammation environment about the prosthesis, with the cytokine production affecting rates of cellular death, osteoclast population, and activity.³⁷ Unfortunately, the understanding of how to minimize wear debris is incomplete; however, the overall incidence of significant osteolysis at the present time is extremely low. Long-term follow-up will provide more answers as to effects wear has on clinical outcomes. Furthermore, newer design concepts such as the plasma discs may prove to eliminate the concern for wear debris.

POSTOPERATIVE CARE

Immediate postoperative care of the TDR patient is much the same as an anterior lumbar fusion. The risks of postope-

rative ileus, deep vein thrombosis, and wound infection are similar.^{3-6,8} Early mobilization and ambulation are paramount for TDR patients—it should be encouraged immediately, the day of surgery. Gentle abdominal flexion exercises can also be started the day of surgery. There is no necessity for formal brace immobilization unless there is a concern for intraoperative iatrogenic fracture. A light corset brace or abdominal binder can be instituted for comfort in the first week postoperatively, and this also helps avoid peak loading of the implant that occurs in extreme positions. After hospital discharge, patients should be instructed to avoid strenuous activity and motions that peak load the implant, particularly lumbar extension. These restrictions should be in place for up to 3 months.

During the first 6 weeks, walking and light lower extremity strengthening exercises are allowed. Core exercise should be avoided until adequate time has been allotted for the abdominal musculature to heal from the surgical approach. Between 2 and 6 weeks postoperatively, patients can be enrolled in an organized physical rehabilitation program focusing on trunk stabilization and lower extremity strengthening.³⁸ Lumbar extension is generally avoided in the first 3 months to allow adequate time for bony ingrowth at the implant-endplate interface. Return to sporting activity can be allowed in the first 3–6 months postoperatively, depending on the patient's progress and the type of sporting activity. There is no consensus as to restricting particular sporting activities. The only study to date on return to sporting participation after TDR shows patients are able to return to high-level competitive sports, professional athletics as well as extreme sports, with peak performance being attained on average at 5.2 months postoperatively.³⁹

Return to work should be made on a case-by-case basis. Depending on the rigors of a particular working environment, some patients can return to work within the first few weeks if their job entails mostly sedentary duties. Other patients whose careers involve more strenuous activities, such as firefighters or heavy laborers, should postpone their return to work until a minimum of 3 months has passed, and may then be evaluated according to their level of rehabilitation. No long-term restrictions are generally required for the TDR implant itself.

Evaluation of the TDR patient should be ongoing. Clinical and radiographic follow-up appointments should be set at 2 weeks, 6 weeks, 3 months, 6 months, 12 months, and annually thereafter to assess the viability of the implant and to screen for osteolysis.

DISCUSSION

Outcomes Data

Over the past decade, there has been a distinct transition in the spine surgery literature toward utilizing the best evidence possible for recommending treatment options. Level of evidence was first introduced to the *Journal of Bone and Joint Surgery* in 2003, with Level I evidence being considered the highest level for a clinical study.⁴⁰ Approximately 16% of spine studies published are considered Level I evidence.⁴¹ Level I studies are defined as being well-designed randomized controlled trials (RCT) with standardized randomization and >80% follow-up, which includes FDA IDE studies of arthroplasty.^{3-5,42}

The early literature on disc arthroplasty consisted predominately of European case series reports. Although not Level I studies, they definitely provided valuable information. The initial experience published by Griffith et al.⁴³ showed statistically significant pain relief in patients implanted with the Charité at nearly 1 year follow-up. The early failure rates were found to be 6.5%. Other positive clinical results of the study also included improvements in walking distance, overall lumbar mobility and even neurologic improvements after disc arthroplasty. A 10-year follow-up study on Charité patients provided continued momentum for the procedure.⁴⁴ This study presented 90% excellent or good clinical outcomes with a return to work rate of >90% in 100 patients. Analyzing the radiographic outcomes, they found a mean flexion/extension range of motion of 10.3°. Other long-term studies from European centers also showed similar success rates with the Charité prosthesis. In 2007, David⁴⁵ published results of 106 patients followed for a mean of 13.2 years. Again, the success rate was high (82% excellent to good) and nearly a 90% return to work, including a return to work of >75% of the heavy laborers. The long-term device-related complication rate was <5%.

Unfortunately, these early studies were only considered fair levels of evidence and they failed to use validated outcomes measures. The US IDE studies on the Charité and ProDisc-L were introduced in the early 2000s and set out to prospectively investigate arthroplasty using a randomized controlled design with validated outcome measures.

The Charité study used a 2:1 randomization ratio with a total of 304 patients—205 investigational patients and 99 in the control group treated with stand-alone ALIF with BAK fusion cages.³ This was a multicenter endeavor with

Table 94.2: Clinical success rates reported in the Charité and ProDisc-L FDA IDE trials at 2-year and 5-year follow-up.

	Success 2 years	Success 5 years
Charité	63.6%	57.8%
ALIF control group	56.8%	51.2%
ProDisc-L	53.4%	48.1%
360 fusion control group	40.8%	41.1%

(IDE: Investigational device exemption).

The results of the two studies cannot be compared or combined as different definitions of success were used.

14 original sites participating in the 2-year study and 8 sites agreeing to participate in a second study following the original patients for 5 years.⁶ Overall success was defined by patients who satisfied all of the following criteria: (1) improvement in ODI by at least 15 points, (2) no device failure requiring an additional surgery, (3) absence of significant complication, and (4) maintained or improved neurologic status over the follow-up. Other secondary measures included VAS pain intensity, SF-36, work status, patient satisfaction, and radiographic data such as ROM. Both the 2- and 5-year Charité studies showed noninferiority to the fusion controls in regard to overall success (Table 94.2). Secondary measures also showed statistically significant improvement in ODI values, VAS pain scores and SF-36 physical component scores for both groups with no statistically significant differences between the groups (Table 94.3). Also, and possibly more important, the rates of patients with full-time employment were higher in the Charité patients (65.6%) compared to the fusion controls (46.5%), which reached statistical significance ($p < 0.05$). Failure rates for the fusion cohorts were twice that of the Charité patients (16.3% vs. 7.8%). All failures in the fusion group were related to pseudarthrosis and they occurred within the first 2 years. Five of the seven Charité failures were found within the first 2 years. Six of these seven failures in the Charité group went on to have posterior instrumentation and fusion for various reasons.

One criticism of the Charité study involved the use of an ALIF with BAK cages as the control arm. However, this was one of the few FDA-approved devices of this type at the time the study was designed. Also, it provided a technique more similar to the TDR procedure in that no additional posterior approach was required. A different control group was selected in the ProDisc-L IDE study.⁸ The control arm for these results was circumferential lumbar fusion using femoral ring allograft and posterior iliac crest autograft

Table 94.3: Secondary measures also showed statistically significant improvement for both TDR and fusion groups at 2-year and 5-year follow-up, with no statistically significant differences between the groups (values for the studies cannot be compared or combined as different versions of VAS and ODI were used).

	<i>Charité</i>	<i>ALIF</i>	<i>ProDisc</i>	<i>360 fusion</i>
VAS pain score				
Pre-op	69.7	70.4	75.9	74.9
2 years	27.2	32.8	36.6	43.3
5 years	31.1	29.1	37.1	40.0
ODI				
Pre-op	48.0	51.1	63.4	62.7
2 years	21.8	27.0	34.5	39.8
5 years	24.0	23.6	34.2	36.2
SF-36 physical				
Pre-op	Not reported	Not reported	31.1	30.9
2 years	Improved 14.2 points from pre-op	Improved 11.2 points from pre-op	42.8	38.8
5 years	Improved 12.6 points from pre-op	Improved 12.3 points from pre-op	42.0	40.1

(VAS: Visual analog scale; ODI: Oswestry disability index; ALIF: Anterior lumbar interbody fusion; TDR: Total disc replacement).

Table 94.4: Clinical success parameters for the ProDisc-L IDE.

<i>Parameter</i>	<i>Criteria</i>
ODI*	>15% improvement compared to baseline value
Device success	No reoperation for device removal or revision and no addition of supplemental fixation
Neurological success	Maintenance or improvement in each evaluation: sensory, motor, reflex, and straight leg raise
SF-36	Any improvement in the physical and mental components composite score compared to baseline values
Radiographic success	No device migration
	No subsidence
	No radiolucency
	No loss of disc height
	Fusion status
	Range of motion: measured from flexion/extension radiographs and restored to within normal range of motion defined to be 6–20° at L3-4 and L4-5; and between 5° and 20° for L5-S1

(ODI: Oswestry disability index; IDE: Investigational device exemption).

*Data also analyzed based on suggested FDA criteria of a minimum 15-point improvement in ODI scores.

A patient had to fulfill all of the criteria to be considered a success.

supplemented with pedicle screws. This Level I study randomized 236 patients in a 2:1 ratio. Clinical success was again the primary outcome measure, utilizing four clinical parameters and seven radiographic parameters (Table 94.4). In the 2-year arm, the ProDisc-L patients showed a statistically significant greater rate of clinical success compared to the 360 fusion controls (54.3% vs. 40.8%; $p < 0.05$). Arthroplasty was found to be superior or at least similar to fusion in all secondary outcome measures. This trend was

maintained in the 5-year follow-up, involving all investigational sites and their patients, with the TDR group having a success rate of 53.7% and the fusion cohorts having 50.0% success rate (with >80% follow-up rates). Patient satisfaction was high in both groups at 5 years, with more patients in the TDR group than the fusion group stating they would have the surgery again. Reoperation rates were higher in the fusion group than the TDR group (12% vs. 8% respectively).

Another noteworthy IDE trial with 2-year published results involved the Maverick device, which is not currently commercially available in the United States at the time of this writing.⁵ This was also a randomized, prospective trial comparing TDR and stand-alone ALIF using metallic cages and bone morphogenetic protein as a graft substitute (rhBMP-2). The study was designed to show superiority of the TDR device rather than noninferiority as with the Charité and ProDisc-L trials. Larger numbers of patients were enrolled as compared to the other IDE studies (405 TDR and 172 controls). Overall success for this trial was defined as ODI improvement >15 points, no worsening of neurologic status, maintenance of disc height, no reoperation, and absence of significant device- or surgery-related complication. The TDR group was found to have statistically superior results compared with the control group in regard to the overall success and all secondary outcome measures. The TDR cohorts were also found to have significantly fewer device- and surgery-related adverse events ($p<0.05$).

There are several other ongoing IDE trials in the United States involving lumbar TDR at varying stages of follow-up. To date, no FDA IDE study on arthroplasty has found the devices to be inferior to fusion or have comparably unacceptable failure rates.

Range of Motion

Radiographic outcomes regarding range of motion after arthroplasty are also a significant discussion point. The longest series of TDR patients shows range of motion in flexion/extension to be on average 10.1° and lateral bending 4.4° at the operative level with mean follow up 13.2 years.⁴⁵ Level I data from the FDA IDE Charité study also show maintenance or improvement of the ROM at the operative level compared to a substantial decrease in the ROM of the fusion segments.⁴⁶ Cadaveric analysis has also shown that spinal motion is similar between intact spines and those implanted with TDR at a single level.²³ Other clinical studies also have shown that the range of motion of adjacent discs was less altered after TDR compared to fusion, in which the TDR level only accounted for a slight loss in total ROM of the lumbar spine, whereas after fusion every level compensated for the loss in motion (mostly at the first cranial adjacent level).⁴⁷

In regard to clinical outcomes, the resultant ROM after TDR has also been linked to better outcome measures. Huang et al.⁴⁸ showed better clinical outcomes in

patients with TDR that maintained at least 5° of implant F/E motion at 8.6 years mean follow-up.⁴⁸ Mid-term 5-year radiographic data from the ProDisc IDE study show the prostheses maintain ROM at the index level with a mean of 7.2°.⁸ Longer-term data is necessary to draw a final conclusion; however, it appears that TDR can maintain adequate ROM at the operative level over time and the better the motion, the better the clinical outcomes may be.

Adjacent Level Disease

A second important measure of clinical outcome is ASD rates after fusion and arthroplasty. Although much of the literature on ASD after fusions has largely been Level II or III evidence, it provides historical controls for the expected rate of ASD after fusion. In a level III study, Ghiselli et al.⁴⁹ determined the rate of symptomatic ASD after fusion to be 16% at 5 years and 36.1% at 10 years. The only prospective study concerning ASD after fusion shows a 10-year rate of ASD to be 38%.⁵⁰

Adjacent segment degeneration after TDR has been found to be less than that of fusion, likely due to a reduction in the transmission of forces to the adjacent segment, which is supported by cadaveric and finite element analyses showing a distinct advantage of TDR over fusion in maintaining normal kinematics of the adjacent disc and facet joints.^{21-23,51} Clinically, the aforementioned long-term level III study on TDR has shown ASD to be <3% at 13 years follow-up.⁴⁵ Based on level I data, TDR has more recently been shown to have statistically significantly lower rates of radiographic changes at the adjacent segment compared to baseline at 5-year follow-up, upward of a threefold difference.⁸ This 5-year IDE data also showed adjacent level surgery rates to be 2% for TDR and 4% for fusion patients. The mid-term results show less severe changes at the adjacent level after TDR compared to fusion, but further long-term comparisons will be needed to prove this definitively translates to a clinical benefit of TDR.

Two-Level Arthroplasty

At the time of this writing, two-level TDR is not yet approved by the FDA. The only current level I study published on multilevel arthroplasty compared two-level TDR with the ProDisc-L device to two-level circumferential arthrodesis in a 2:1 randomization trial.²⁷ The clinical success was based on the parameters previously mentioned for the single-level IDE study. Similar to the single-level study, patients in the TDR group had better outcomes in regard

to multiple measures—ODI, SF-36, and VAS pain levels. Clinical success was obtained in 73.2% of the arthroplasty patients and 59.7% of the fusion patients. Based on these results, noninferiority of two-level arthroplasty was concluded. Although FDA approval may occur based on the 2-year and longer data, insurance coverage will likely remain an issue even if FDA approval is obtained for the procedure.

Economic Impact

Finally, it is important to discuss the economic implications of TDR. The most appropriate outcome-based control for clinical comparison studies is a circumferential arthrodesis utilizing the anterior interbody technique. For anterior spinal fusion, the use of rhBMP-2 significantly alters the hospital costs; therefore, it is difficult to directly compare procedures. At many institutions, the use of rhBMP-2 in anterior lumbar fusions has been exceedingly more common. In general, TDR costs are similar to circumferential fusion (utilizing either anterior inter body or transverse inter body technique) without the use of rhBMP-2.¹² Accounting for the cost of rhBMP-2, TDR is considerably less expensive than anterior/posterior fusion. In comparing one- and two-level TDR to circumferential fusions, Levin et al.¹⁰ found that for the one-level comparison there was a significant difference in charges, with the fusion costing >50% more in operating room charges than TDR. The two-level comparison showed similar total charges between the groups. An economic model comparing both hospital costs and third-party payer costs for arthroplasty and three different types of fusion also showed that the overall economic effect of single-level arthroplasty is equal if not less than a fusion.¹¹

CONCLUSION

Lumbar arthroplasty may prove to be one of the more significant advances in the surgical treatment of functionally disabling degenerative disease of the lumbar spine. In an ideal future scenario, we will have noninvasive diagnostic metrics to differentiate between painless and painful degenerative discs, minimally invasive biologic interventions for early and intermediate phases of degeneration that can biochemically reverse the process and physiologic disc replacement implants for more advanced degenerative discs that have sustained irreversible structural damage; however, the science is not there yet for any of these three stages. Research is ongoing in diagnostic analysis of the chemical

products of disc metabolism either through harvest by a needle aspiration or by quantifying signal change on MRI. Future research should find other noninvasive means of identifying patients who would benefit from nonsurgical and surgical intervention. Currently, there are multiple research paths all aimed toward earlier intervention with biologic treatment. On the surgical front, several next-generation arthroplasty implants are being developed with shock absorption and viscoelastic response designed into materials and designs.

Through examination of the highest levels of current evidence in the literature, we can conclude that current arthroplasty designs are viable and have performed similarly to, if not better than, lumbar fusion. The implants are proven safe, with a lower reoperation rate than fusions. In regard to adjacent level degeneration, both in vivo and in vitro studies show that arthroplasty provides a protective benefit for the adjacent intervertebral disc level. The “perfect disc” is evolving from multiple ongoing clinical trials, and arthroplasty has proved itself worthy of continued clinical use.

INTRODUCTION

Patients with cervical radiculopathy who are refractory to an adequate course of nonoperative therapy or have progressive neurologic deficits can be treated surgically. Decompressive surgery in these symptomatic patients can be completed successfully via an anterior or posterior approach.

An anterior surgical approach with anterior cervical discectomy and fusion (ACDF) is often preferred for patients with central and paracentral disc herniations or ventral thecal sac compression from osteophytes. The goals of ACDF are to decompress the neural elements, provide permanent segment stabilization, restore cervical lordosis, and preserve anatomical disc space height. However, the kinematics at levels adjacent to a fusion are altered and it is postulated that these changes may lead to an increased risk of adjacent-segment degeneration.

Cervical disc arthroplasty achieves adequate anterior decompression of the neural elements and also allows for preservation of physiologic motion patterns following surgery. This additional benefit compared to ACDF may reduce the incidence of degenerative disc disease at adjacent cervical motion segments following anterior cervical decompressive surgery.

BIOMECHANICS OF ARTHROPLASTY

For more than half a century, degenerative cervical spondylosis has been addressed from an anterior surgical

approach.¹⁻³ With refined operative techniques and modern implants, fusion rates following single-level ACDF have surpassed 95%.⁴ Several widely publicized, long-term follow-up studies, however, have raised concern regarding the rate at which these patients developed adjacent segment degeneration. One study reported that the incidence of *radiographic* adjacent segment degeneration was as high as 92% within 5 years of anterior cervical arthrodesis.⁵ Hilibrand presented data demonstrating that >20% of patients who underwent ACDF developed *symptomatic* adjacent level degeneration within 10 years of their index operation.⁶

The debate is ongoing, however, as to whether this patient population is naturally predisposed to adjacent level degeneration or whether the fusion actually promotes the accelerated degeneration. Several biomechanical, cadaveric models lend credence to those who espouse the latter.^{7,8} These and other studies have documented that rigid fixation across a previously mobile segment increases the shear stress across the adjacent disc spaces and causes elevations in intradiscal pressures—both phenomena that could promote degeneration at the adjacent level.^{9,10} Other well-designed biomechanical models have suggested that intradiscal pressure is not affected at adjacent levels or is only accelerated to a statistically significant degree following two- and three-level ACDF.^{11,12} However, others suggest that intradiscal pressure and range of motion at adjacent levels are unaltered by anterior cervical fusion, instead proposing that adjacent segment pathology should

represent the natural history and progression of cervical spondylosis.¹³ There are studies in the surgical literature as well that evaluate evidence from prospective clinical trials that compare arthroplasty with traditional ACDF. These studies conclude that maintaining cervical segmental mobility not only reduces radiographic evidence of adjacent level degeneration, but also decreases the incidence of symptomatic adjacent segment disease.¹⁴⁻¹⁹

Regardless, the universal objective of minimizing adjacent segment disease has provided the industrial impetus to develop motion-sparing implants and alternatives to fusion. Although a number of implants produced by various manufacturers are currently available, the underlying objective of each design remains constant—to serve as a fixed, interbody spacer that preserves cervical segmental motion and approximates anatomic alignment through a full range of motion.²⁰ Discussion regarding design details such as devices engineered to limit translation in certain planes or to optimize the center of rotation across the arthroplasty is beyond the scope of this chapter. Until prospectively collected data demonstrate statistically significant differences in outcomes across arthroplasty devices, the choice of implant will remain largely up to the surgeon's discretion. As discussed below, however, certain devices are manufactured from materials that may preclude imaging with cervical magnetic resonance imaging (MRI), and this may dictate which device is selected for implantation.

INDICATIONS FOR ARTHROPLASTY

Cervical arthroplasty is used as a motion-sparing alternative to ACDF for the treatment of single- or two-level degenerative disc disease or when adjacent to a prior ACDF causing a refractory radiculopathy or early spondylotic myelopathy between levels C3-4 and C7-T1.²¹⁻²⁴ At this time specific cervical arthroplasty devices are approved for single- and two-level degenerative disc disease of the subaxial cervical spine in patients who have failed at least 6 weeks of conservative therapy.^{23,25,26}

As one of the primary objectives of the artificial disc is its ability to preserve motion, patients with incompetent posterior elements are typically excluded from consideration of a motion-sparing approach as the facets are not replaced with the arthroplasty procedure. Therefore, patients with congenital, degenerative, iatrogenic, or traumatic facet defects are not ideal candidates for arthroplasty.²⁷ Otherwise, absolute contraindications to artificial disc implantation are few, but include cervical kyphotic deformity, active discitis or osteomyelitis, and radiographic instability

on dynamic cervical films.²⁸ Most trials considered age >60 years, uncontrolled diabetes, a history of rheumatoid arthritis, chronic steroid use, renal insufficiency, osteoporosis, active malignancy, or other metabolic conditions with poor bone quality relative contraindications to arthroplasty.^{15,17,23,29-31} The Food and Drug Administration (FDA) investigational device exemption (IDE) arthroplasty studies also excluded patients with evidence of severe spondylosis → 50% loss of disc height, bridging osteophytes, and <2° of motion—at the surgical level.^{15,29,30,32} Arthroplasty, particularly with stainless steel implants, should also be avoided in patients with conditions such as cervical syringomyelia or other pathologic conditions that require periodic surveillance MRI since the arthroplasty materials often create shadow artifact on MRI.

Ideal candidates for cervical disc arthroplasty are younger patients with good bone quality and no evidence of facet joint arthropathy or instability.

PREOPERATIVE EVALUATION

Symptoms of degenerative cervical disc disease may range from neck pain alone to pain in a particular dermatomal distribution or from paresthesias in the upper extremities to deterioration reported in dexterity or handwriting.^{25,26,33} A thorough neurological examinations of patients with these symptoms should include motor, sensory, and reflex examination. Ideal candidates for cervical discectomy are those patients with objective signs and/or clinical symptoms of cervical spinal radiculopathy or mild myelopathy. Myotomal weakness, sensory deficits, and diminished reflexes are objective clinical findings of radiculopathy.³⁴⁻³⁶ More diffuse weakness, hyper-reflexia, the presence of pathologic reflexes (i.e. Hoffman's sign, clonus), urinary retention, and gait instability are all objective findings suggestive of cervical myelopathy.³⁷ Given the widespread availability and noninvasive nature of MRI, many of the patients referred for cervical spine evaluation will have already undergone this study (Figs. 95.1A and B). Computed tomography (CT) myelogram has been relegated for use predominantly in situations where a patient is unable to undergo (e.g. the presence of a pacemaker or implantable cardioverter defibrillator) or to tolerate (e.g. claustrophobia, morbid obesity) an MRI.

Once a patient is diagnosed with compressive cervical pathology amenable to surgical intervention from an anterior approach, the spine surgeon must then determine whether the patient is a candidate for arthroplasty. Although not required, some surgeons also obtain CT

Figs. 95.1A and B: Preoperative magnetic resonance imaging (MRI) cervical spine (sagittal T2-weighted image) reveals a disc herniation at C5-C6 causing cord compression. Note evidence of T2 signal change within the cervical spinal cord at this level. (B) Preoperative MRI cervical spine (axial T2-weighted image) reveals cord compression from a central disc herniation at C5-C6.

Fig. 95.2: Preoperative dynamic lateral radiographs reveal no evidence of instability on flexion and extension.

scans of the cervical spine prior to artificial disc replacement to evaluate the integrity of the bony elements, to identify potentially cumbersome anterior osteophytes, and to document the absence of significant facet hypertrophy. In our practice, dynamic cervical radiographs in neutral, flexion, and extension are also obtained not only to review the individual patient's anatomic cervical alignment in the presence of an axial load, but also to identify kyphotic deformities or sagittal translation/instability >3.5 mm, which precludes an arthroplasty (Fig. 95.2). Electromyography (EMG) plays a limited role in the diagnosis of cervical radiculomyelopathy and does not guide the surgeon

in differentiating those patients who may benefit from arthroplasty versus a standard ACDF.³⁸⁻⁴¹

SURGICAL TECHNIQUE

The cervical arthroplasty technique is somewhat similar to an ACDF but several important differences need to be highlighted. Before surgery, the anteroposterior dimensions and the disc space height of the involved segment should be radiographically measured to determine the proper implant size.

A standard approach to the anterior cervical spine is undertaken. A transverse skin incision is made over the target interspace. Dissection is carried out medial to the carotid sheath and lateral to the trachea and esophagus to arrive at the anterior cervical spine. The omohyoid muscle is divided, if necessary in order to improve retraction.

Next, the level of the disc space is confirmed using fluoroscopy. The longus colli muscles are elevated subperiosteally off the lateral margins of the disc space and self-retaining retractors are placed. The anterior longitudinal ligament is also removed but dissection is not extended past the mid-portion of the vertebral bodies adjacent to the disc space. Gentle intervertebral distraction may be performed using vertebral body pin distraction with the goal of maintaining anatomical disc space height.

An incision is made in the anterior annulus fibrosus and the disc material is removed using pituitary rongeurs and curettes. The cartilaginous endplates are removed using curettes and the lateral margins of the disc space

Fig. 95.3: Postoperative anteroposterior image shows placement of the cervical arthroplasty device in the midline of the index level.

are exposed. It is important to preserve the bony endplate integrity. Hypertrophied uncovertebral joints are thinned with a high-speed burr and the neural foramina are enlarged using a thin-footed Kerrison. The posterior annulus and the posterior longitudinal ligament are removed with Kerrison and curettes. The central spinal canal and neural foramina are decompressed. The depth of the vertebral body is precisely measured using a caliper. Selection of the implant size is based on the approximate depth and height of the interspace. Special attention is given to not over-distract the interspace or oversize the prosthesis, as supra-physiologic disc space distraction will likely prevent anatomical segmental motion. The implant is positioned and fit into the center of the interspace and may be additionally secured to the adjacent vertebral bodies with screws (Fig. 95.3) or rails depending on the implant's design.

On a technical note, exquisite hemostasis is important to the long-term functional maintenance of the arthroplasty procedure. Using bone wax or a flowable gel foam with thrombin, all posterior osteophyte resection areas should be treated to prevent hematoma formation prior to placement of the prosthesis. Similarly, once proper placement of the implant is achieved, hemostasis of the anterior bony surfaces must be obtained to avoid both retropharyngeal hematoma in the acute postoperative period and heterotopic ossification in the long term. The formation of even a small amount of hematoma at a retained ligament near the disc space may act as a nidus for calcification formation and subsequent heterotopic ossification development.

OUTCOMES

The follow-up reports of cervical arthroplasty are not as lengthy as outcome reports for ACDF, which have more than two decades of follow-up.⁴² Still, the promising results of several FDA IDE arthroplasty trials prompted the North American Spine Society (NASS) in 2010 to state, "ACDF and total disc arthroplasty (TDA) are suggested as comparable treatments, resulting in similarly successful short term outcomes, for single-level degenerative cervical radiculopathy."⁴³ More recent findings suggest that even this guidance may be conservative as the superiority of arthroplasty over ACDF on many primary outcome measures is found when pooling the (largely homogeneous) data from several FDA IDE trial results.¹⁹

There are several prospective, randomized, multicenter US FDA IDE trials with results data ranging from 2 to 5 years, each comparing validated outcome measures—neck disability index (NDI), visual analogue scale (VAS) neck and arm pain, Short Form (36) Health Survey (SF-36), adjacent segment disease, repeat operation, range of motion, and adverse events—of a variety of artificial disc implants to standard ACDF.^{15,17,24,29,30,32,44} All of the US FDA IDE protocols published so far compared single-level artificial disc replacement to single-level ACDF.

In 2009, Murray et al. published the results of a prospective, randomized trial evaluating the ProDisc-C (Depuy Synthes Companies, Raynham, MA) across 13 centers.³² At 2-year follow-up, all 209 patients enrolled in the trial reported improvement in their NDI, VAS, and SF-36 scores with approximately 90% of patients reporting sustained improvement in their neurologic symptoms. The authors documented, however, a statistically significant reduction in the number of subsequent operations and in the quantity of pharmacologic agents prescribed to the 103 patients who underwent ProDisc-C implantation. This led the investigators to conclude that outcomes derived from implantation of the ProDisc-C device were at least equivalent to ACDF.

Phillips et al. in 2013 reported the results of a prospective, randomized, controlled investigation of the Porous Coated Motion (PCM) Cervical Disc (NuVasive, Inc., San Diego, CA).²⁴ In this study, 342 patients were enrolled (189 randomized to PCM, 153 to ACDF) and followed 2 years postoperatively as part of the device's US FDA IDE clinical trial. In contrast to other cervical disc arthroplasty devices, enrollment in the trial and subsequent FDA

labeling allowed for treatment of degenerated levels with PCM adjacent to prior ACDFs. Radiographic findings at 2 years showed a mean range of motion of 5.7° for the PCM and 0.8° for the ACDF group. Significant improvements in clinical outcomes were seen in both groups. However, NDI, dysphagia scores, patient satisfaction, and overall success (a composite endpoint including minimum 20% NDI improvement, no major complications, no neurologic worsening, no secondary surgical procedures, and meeting radiographic criteria of motion) were all statistically significantly improved for PCM compared to ACDF (all $P < 0.05$). The final comparison of overall success resulted in a superiority finding (rather than noninferiority) for PCM compared to ACDF (75.1% vs. 64.9%, respectively). When examining the subgroup of patients from each randomization who had undergone a previous ACDF, the findings were similar to the overall findings, though with attenuated clinical improvements in each group (PCM and ACDF).

Another multicenter, prospective, randomized trial that implemented an FDA IDE approved protocol was the Kineflex C (SpinalMotion, Mountainview, CA) trial.³⁰ In this trial, Coric et al. demonstrated noninferiority of artificial disc replacement compared to ACDF to treat single-level cervical spondylosis. At 24 months follow-up, the vast majority of all 269 patients reported significant and sustained improvement in NDI and VAS scores, and although there was a statistically significant increased incidence of radiographic adjacent segment degeneration among the ACDF group, there was no statistically significant difference in the rate of adjacent-level operation or repeat index-level operation.

By contrast, Sasso et al. reported that at 4 years, the outcomes of patients who underwent single-level arthroplasty with the Bryan Cervical Disc (Medtronic Spinal and Biologics, Memphis, TN) were statistically superior to those randomized to standard anterior cervical fusion with allograft and plate stabilization.⁴⁴ These findings reiterated the conclusion previously published by Heller et al. documenting the initial, 24-month outcomes data from the Bryan Cervical Disc trial.²⁹ Presenting clinical follow-up data on 319 prospectively randomized patients, Sasso et al. found that those patients who underwent arthroplasty had sustained statistically superior outcomes across virtually all validated outcome measures at 4 years, and while adjacent-segment degeneration was not specifically addressed, the rate of secondary surgical procedures at the index level was $<5\%$ in both groups.

Fig. 95.4: Postoperative dynamic lateral radiographs demonstrate the range of motion is maintained at the C5-C6 level.

In 2010, Burkus et al. published results of the largest FDA IDE arthroplasty trial, which enrolled >500 patients across 32 investigational sites who were followed for 5 years following either single-level Prestige ST Cervical Disc arthroplasty (Medtronic SofamorDanek Memphis, TN) or standard ACDF.^{17,38} This manuscript similarly served as an update to previously published 2-year outcomes data by the same investigators.¹⁵ Statistically significant improvements in NDI, SF-36, and VAS neck and arm pain scores were noted by the authors as early as 6 weeks postoperatively in the arthroplasty group and shown to be sustained through the 5-year follow-up appointment. The researchers also demonstrated that the Prestige disc effectively maintained more than 6° of cervical segmental motion at 60 months (Fig. 95.4), whereas ACDF restricted segmental range of motion to less than half a degree. Interestingly, despite no statistically significant difference between the investigational and control groups between either subsequent operation for adjacent-segment disease or rate of revision of the index surgery, the patients who underwent arthroplasty reported statistically superior neurologic outcomes.

One recently published study evaluated the combined data from three FDA IDE single-level arthroplasty trials—Prestige ST, Bryan, and ProDisc-C—with at least 2 years of clinical follow-up.¹⁸ Upadhyaya et al. reported rates of fusion for ACDF as better than 95% and noted that both investigational and control groups reported improvement in NDI, SF-36, and VAS pain scores postoperatively. Neurologic success, however, as defined by sustained

improvement in motor, sensory, or muscle stretch reflex examinations, was noted to be statistically superior in the arthroplasty cohort. The authors also validated cadaveric, biomechanical studies by demonstrating preserved segmental range of motion in the arthroplasty group. The authors did not find a statistically significant difference in the rate of adjacent segment disease at the 2-year interval.

While all FDA IDE trial publications to date have evaluated single-level arthroplasty, there is some data beginning to emerge that evaluate outcomes of multilevel arthroplasty. In 2010, Cardoso and Rosner presented data based on the 12-month clinical outcomes assessments that multilevel cervical arthroplasty was both safe and effective in treating cervical radiculopathy and myelopathy.⁴⁵ Similarly, a French group published the results of >50 patients who underwent two-level or more arthroplasty, the vast majority of whom (>94%) reported sustained clinical neurologic improvement to an extent similar to a cohort of nearly 200 patients who underwent single-level arthroplasty.⁴⁶ A third study by Pimenta et al. examined multiple- and single-level arthroplasty outcomes, as part of a prospective, consecutive series of 229 patients treated with PCM for an FDA pilot study.⁴⁷ In this study, the authors found statistically significant improvements in disability for multilevel compared to single-level arthroplasty, with all other outcomes equivalent between the two. However, there is some evidence to suggest that multilevel arthroplasty triggers an increased incidence of heterotopic ossification.^{48,49} Of note, early radiographic evidence of heterotopic ossification does not appear to diminish functional outcomes, at least through mid-term follow-up.^{50,51} The long-term clinical implications, possibly related to an increased incidence of spontaneous and unintended fusion, remain undefined.

Overall, cervical arthroplasty has proven to be a viable alternative to traditional fusion operations in improving clinical symptoms of radiculopathy and in preventing the progression of myelopathy. Recent results also suggest that arthroplasty may be superior to ACDF in the overall success and several other parameters when data from the FDA IDE studies are pooled.^{18,19} Importantly, none of the recently published FDA IDE trial results have reported catastrophic events related to the implantation of an artificial disc. Clinical outcomes data with >48 months of follow-up are available for three of the four artificial prostheses described above, and in all cases the follow-up rate

was <80%. Longer-term follow-up (>10 years) is still not yet available from the US FDA IDE trials.

■ COMPLICATIONS

For cervical arthroplasty, anterior approach-related complications including dysphonia and dysphagia are similar to the rates reported in the ACDF literature. Additional complications associated with the implant itself are important to note. These include the rare incidence of implant migration and subsidence.⁵² There is a case report of incomplete paraplegia following dislocation of an artificial disc device into the spinal canal with resultant spinal cord compression.⁵³

Furthermore, heterotopic ossification (HO) after cervical arthroplasty can limit the mobility of an artificial disc. Tu et al. analyzed a total of 107 levels of Bryan disc arthroplasties placed in 75 patients in Taiwan.⁵⁴ Heterotopic ossification was identified in 60 levels (56.1%) by CT scanning. Furthermore, Wu et al. looked at the difference in HO formation between one- and two-level cervical arthroplasty patients.⁴⁸ Their results revealed a significantly higher rate of HO formation (75% vs. 40.5%) in the two-level arthroplasty group in the Taiwanese population. Another study by Pimenta et al. examined the incidence of HO at an average follow-up of 4.5 years (range 1–6 years) in 158 patients who received the PCM disc at 272 levels.⁵⁵ The authors found an HO rate of 7.7% (20 levels). In 91% of patients who developed HO, immediate postoperative imaging was reviewed and remaining osteophytes were observed where HO eventually formed, suggesting the need for diligent surgical technique in the intraoperative management of osteophytes. No relationship between HO and clinical deterioration was found. The long-term effects of HO, however, do warrant further investigation. Certain ethnic subgroups, such as patients of Asian heritage, may be more prone to HO formation. Early HO can potentially be avoided by administering nonsteroidal anti-inflammatory drugs in the immediate postoperative period.

■ CONCLUSION

Cervical arthroplasty is a safe and effective alternative to standard ACDF in addressing single-level degenerative cervical spondylosis in the setting of a corresponding clinical radiculopathy or mild myelopathy, based on four level I evidence studies. Recent investigations have

shown that multilevel use may be equivalent with single-level treatment. As with all surgical procedures, patient selection in cervical arthroplasty is critical in optimizing postoperative symptomatic relief. The thorough preoperative radiographic evaluation includes a cervical MRI or CT myelogram. Dynamic cervical films are recommended to identify concomitant baseline cervical instability or arthritic facet pathology that may predict a poor surgical outcome following arthroplasty. Recent data evaluating outcome measures up to 5 years after cervical arthroplasty suggest that one-level artificial disc replacement surpasses ACDF in long-term symptomatic relief while at the same time preserving focal anatomic segmental range of motion and possibly reducing the incidence of adjacent segment disease.

KEY POINTS

- Cervical arthroplasty is a safe and effective alternative to ACDF in addressing single-level degenerative cervical spondylosis in the setting of a corresponding clinical radiculopathy or myelopathy.
- Cervical arthroplasty preserves anatomic focal segmental range of motion and may reduce the incidence of adjacent segment disease when compared with ACDF.
- Preoperative MRI or CT myelogram should be used to confirm the etiology of cervical radiculopathy or mild myelopathy. Dynamic cervical films should be used as adjuncts in accurately identifying patients who may be suitable for arthroplasty.
- To optimize surgical outcome, the surgeon must take care to size the artificial disc appropriately and to position the graft in the center of the disc space. Above all, especially in patients with radiculopathy, there is no substitute for delicate, thorough nerve root decompression that extends to the uncovertebral joints bilaterally.
- Compared to single-level arthroplasty, initial studies evaluating surgical outcome in two-level cervical arthroplasty suggest that multilevel artificial disc replacement is effective in reducing radicular symptoms, but may be associated with higher rates of heterotopic ossification.

- Wu et al. compared surgical outcome between one- and two-level cervical arthroplasty in a Taiwanese population. Although their prospectively collected data suggest that multilevel artificial disc replacement is similarly effective in reducing radicular symptoms, the authors raise the concern that two-level arthroplasty had a tendency to promote more extensive postoperative heterotopic ossification and appeared to preserve less anatomic range of motion.
- Mummaneni PV, Robinson JC, Haid RW Jr. Cervical arthroplasty with the PRESTIGE LP cervical disc. *Neurosurgery*. 2007;60(4 Suppl 2):310-4; discussion 314-5.
- To optimize surgical outcome, the surgeon must take care to size the artificial disc appropriately and to position the graft in the midline with the patient in normal, anatomic cervical lordosis. Above all, especially in patients with radiculopathy, there is no substitute for meticulous nerve root decompression that extends to the uncovertebral joints bilaterally.
- Gwynedd E, Sekhon LH, Sears WR, et al. Complications with cervical arthroplasty. *J Neurosurg Spine*. 2006;4(2):98-105.
- The complication rate associated with cervical arthroplasty is estimated to be 6% per level. Strict adherence to proper surgical technique should minimize graft migration and complications associated with the anterior surgical approach. Heterotopic ossification and spontaneous arthrodesis are rare, but negate the benefits of a motion-sparing procedure when it occurs. Postoperative nonsteroidal anti-inflammatory medications may reduce the incidence of heterotopic ossification and unintended fusion.
- Upadhyaya CD, Wu JC, Trost G, et al. Analysis of the three United States Food and Drug Administration investigational device exemption cervical arthroplasty trials. *J Neurosurg Spine*. 2012;16(3):216-28.
- The authors analyzed the combined results of the three randomized US FDA investigational device exemption trials comparing arthroplasty with anterior cervical discectomy and fusion (ACDF) for single-level cervical disc disease with a 2-year follow-up period. A total of 1,213 patients were randomized into two treatment arms: 621 patients received an artificial cervical disc and 592 were treated with ACDF. The arthroplasty group demonstrated superior results at 24 months in neurological success and also had a lower rate of secondary surgeries. At the 2-year time point, the reoperation rate for adjacent level disease was lower for the arthroplasty group when the combined dataset was analyzed using a fixed effects model.

INTRODUCTION

Degenerative diseases in the thoracic spine include thoracic disc herniation, ossification of the posterior longitudinal ligament (OPLL), and ossification of the ligamentum flavum (OLF) causing thoracic myelopathy. In daily clinical practice, these diseases are less frequently encountered compared to diseases of the cervical or lumbar spine. Thoracic disc herniation may develop in one out of one million persons and often presents nonspecific symptoms such as dorsal pain and band-like trunk pain, in addition to lower-extremity paralysis. These symptoms can lead to confusion with a lumbar spine disease, which makes diagnosis difficult in some cases.

Thoracic OLF develops mainly in the lower thoracic vertebrae due to involvement of dynamic factors of the spine, while thoracic OPLL often develops in mid-level thoracic vertebrae, at the apex of physiological kyphosis. The peak age of onset is 40 years old or more, in middle-aged or elderly persons, and there is no clear gender difference. Conservative treatments for thoracic degenerative diseases are often ineffective and surgical treatment is often required. However, such surgery is technically demanding. Here, we discuss the symptoms, diagnoses and treatments including surgical approaches for thoracic myelopathy in patients with thoracic disc herniation.

SYMPTOMS

Many patients with thoracic disc diseases first visit a hospital for nonspecific back pain, band-like trunk pain

or sensory impairment in the lower extremities. These symptoms may be bilateral or unilateral depending on the side of spinal cord compression. Many patients complain lower-extremity muscle weakness and gait disorder, rather than chest symptoms, and are diagnosed with a lumbar spine disease. These symptoms generally aggravate, but often after repeated improvement and aggravation. However, in rare cases, they may rapidly aggravate after a mild injury such as a fall. Spastic paralysis of the lower extremity may occur after aggravation of trunk symptoms, or paralysis may develop depending on body position in the early morning, even without an injury.

Sensory disturbance at the lesion site and below lower-extremity muscle weakness, spastic gait, deep tendon hyper reflexes, positive Babinski reflex and ankle clonus, bladder and rectal disturbance may also be present. Since the clonus and epi conus are located in the thoracolumbar area, more complicated symptoms may also be observed in the lower thoracic lesions. Lower-extremity deep reflex decreases and atrophy of lower-limb muscle may occur along with a decrease in leg strength in such cases.

DIAGNOSIS

Ossification of ligaments and bony spurs of thoracic vertebrae are often unclear on plain X-ray films because the costal bones are located in the thoracic vertebral area.

Therefore, magnetic resonance imaging (MRI) should be performed when a thoracic lesion is suspected based on neurological symptoms. However, even if MRI shows a thoracic compressive lesion, it cannot be clearly judged whether the lesion is due to a herniation, a bony spur, or ossification of the ligament. In such cases, computed tomographic (CT) examination is required before deciding the surgical indication, since CT enables differential diagnosis of disc herniation and a bony spur. When the lesion is soft disc herniation, a posterior approach enables sufficient removal, while an anterior approach is used for a bony spur. A posterior approach for a bony spur requires cost-transversectomy to remove the costal process and costal base. Thus, establishment of the appropriate operative strategy requires the use of CT.

TREATMENT

Conservative treatment is almost always ineffective for spinal cord paralysis caused by a thoracic degenerative disease, and thus surgical treatment is necessary. The results of surgery for the thoracic spinal cord compression in patients with spondylosis and thoracic OPLL are not favorable, but those for thoracic disc herniation are comparatively good. However, the approach to the spinal cord is often more difficult than that in case of a cervical spinal pathology. This is because of the presence of physiological kyphosis in the thoracic spine, in contrast to cervical and lumbar spine, and thus it is difficult to ensure spinal decompression only through a posterior approach. In an anterior approach, decompression of the spinal cord is technically demanding because of the adhesion of the dura mater and ossified ligament, a narrow visual field after a vertical split of the sternum in the upper thoracic spine and the removal of costal bones in the mid to lower thoracic spine. In the following section, we discuss the details of the anterior and posterior approaches for the treatment of thoracic degenerative diseases.

SURGICAL TREATMENT

Anterior Approach

In most cases, a spine surgeon should be able to perform an anterior approach to the thoracic spine with little support from a thoracic surgeon. The important points in an anterior approach¹ to thoracic disc herniation,

especially for middle to lower thoracic disc herniation, are as follows:

Anesthesia

An anesthesiologist performs one-lung ventilation with as little ventilation of the lung on the surgical side as possible. The use of a double-lumen intratracheal tube is recommended.

Choice of Approach Side

The approach should be performed on the side of the herniation. In a second surgery, the approach should be from the side opposite to that used in the previous surgery. If both sides are available, the left side is preferable because the aorta on the left side can be mobilized more easily than the vein on the right side.

Position of the Patient

A lateral position should be used, with a pillow placed beneath the axilla to prevent axillary nerve paralysis, and with the upper extremity in the upside placed on a cedar plate. In addition, the hip and knee joints on the down-side are held in slight flexion to reduce tension of the iliopsoas muscle. The lower extremity in the upside is held in an extended position or in slightly flexed position, with a pillow placed between the lower extremities. A sponge pad should be placed beneath the fibular head of the lower extremity in the downside to prevent peroneal nerve paralysis (Fig. 96.1).

Choice of Costal Bone to be Removed

The costal bone one or two level cranial from the vertebral body or vertebral disc to be exposed should be removed. Especially, for decompression, the costal bone two levels above should be removed to ensure a better surgical field (Fig. 96.2).

Approach to T5/T6

For the approach to T5/T6, the head of the rib of T6 should be removed. A needle inserted into the vertebral disc is used for level confirmation. Segmental arteries of the upper and lower vertebral body are ligated if necessary (Figs. 96.3A and B).

Fig. 96.1: Body position in the approach to middle and lower thoracic vertebrae. The recurvatum position in the lumbar vertebral area makes it easier to perform procedures for the vertebral disc and vertebral body in the thoracic vertebral area.

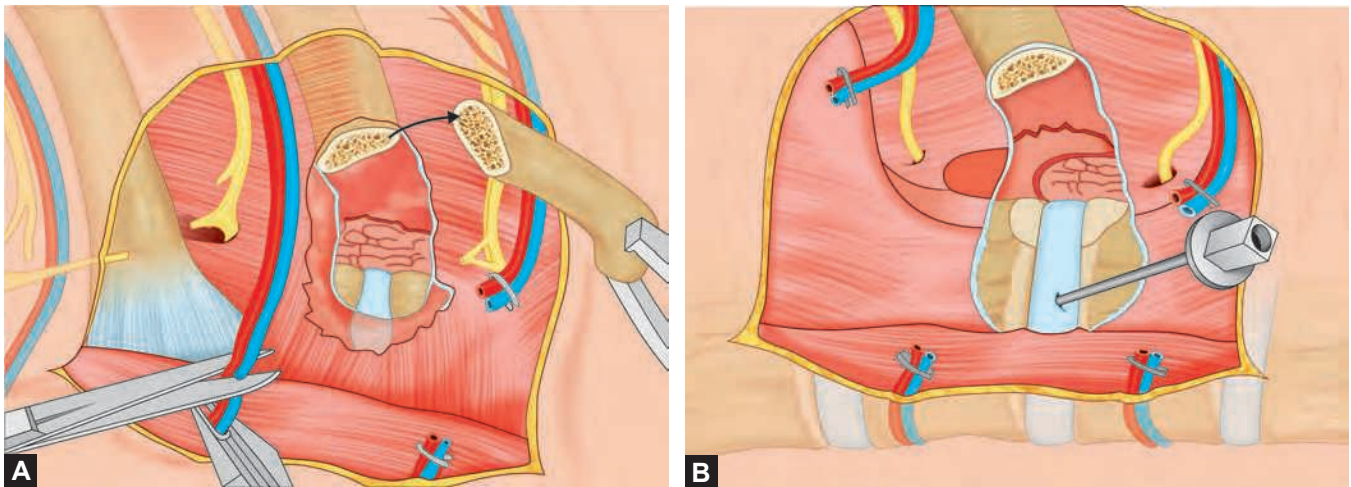

Fig. 96.2: Removal of the No. 7 costal bone. In the approach to middle to lower thoracic vertebrae, removal of the No. 7 costal bone from the rib cartilage to the angle of the rib is preferable. When backward curvature is present and sloping of the costal bone is observed, the No. 5 costal bone should be removed to ensure a good procedure for a curved apical vertebra.

Figs. 96.3A and B: Intervertebral approach. Removal of the head of the rib.

Figs. 96.4A and B: Intervertebral approach. Destruction of the vertebral body and removal of the vertebral disc.

Completion of Spinal Decompression

Hemorrhage can be reduced when the vertebral body is dissected and exposed subperiosteally. In the approach for T5/T6, the intervertebral space is confirmed by sliding a raspatorium posterior to the intervertebral disc, and one-third of T5 and T6 vertebrae are excised using an air drill. After thinning of the posterior wall of the vertebral body, the cortex bone is removed using a sharp curette. The vertebral disc is then removed and spinal cord decompression is completed. The important point of this procedure is that the bone in the deep side should be removed first because the dura mater could bulge when the bone in the front side is removed first, after which decompression of the deep part becomes difficult (Figs 96.4A and B).

Bone Graft

After decompression of the spinal cord, the costal bones removed at the beginning of the procedure are trimmed and transplanted (Figs. 96.5A and B).

Posterior Approach

Regarding degenerative disease in the thoracic spine, a conventional laminectomy is insufficient in many cases when a soft disc and a bone spur are to be removed from patients with thoracic disc herniation and spondylosis, respectively. Soft disc herniation may be removed after wide laminectomy or partial removal of the pedicle.

Figs. 96.5A and B: Bone transplantation.

Fig. 96.6: A thoracic vertebra shown from behind, showing the removal range of the costal process and costal bone. Arrow represents bony section to be resected.

Fig. 96.7: An axial image of a thoracic vertebra, showing the removal range of the costal process and costal bone, in addition to the visible range from the posterolateral side.

However, these procedures are insufficient for the removal of a bone spur, and thus, the removal of the transverse process and the rib head are required. The scheme for this costotransversectomy^{2,3} is shown in Figures 96.6 and 96.7. In this approach, the unilateral thoracic intervertebral joint should be removed completely and fixation should be performed using an instrument after decompression.

Representative Case

In this case, preoperative MRI and myelopathy CT showed that the spinal cord was displaced to the left side by a herniation that ruptured to the right side of the spinal canal at the T5/T6 level (Fig. 96.8). The herniation was removed by a posterior approach, and good decompression of the spinal cord was obtained (Figs. 96.9 and 96.10).

Fig. 96.8: Preoperative T5/T6 herniation in a representative case.

Fig. 96.9: Postoperative myelopathy computed tomography in a representative case.

Fig. 96.10: Postoperative magnetic resonance imaging in a representative case.

INTRODUCTION

Thoracoscopic surgery is often credited to Jacobeus, where he described in 1910 a thoracoscopic lysis of tuberculosis-related lung adhesion. In actuality, however, Cruise in Dublin was described in an article published in 1879 as performing an endoscopic examination of a chest fistula.¹ Eventually, modern thoracoscopy was developed and its use in the thoracic spine was popularized by Mack et al.² Use of thoracoscopy then expanded to numerous other spinal disorders including but not limited to thoracic discectomy, corpectomy (for trauma, tumor, degenerative change/stenosis, instability, or infection), biopsy, kyphosis surgery (i.e. anterior release for deformity), and scoliosis surgery.³⁻²⁰ Thoracoscopy is also widely used for performing sympathectomies for hyperhidrosis.^{11,21-23} More unusual indications for a thoracoscopic approach to the spine include thoracoscopic approaches for extra-axial tumors (e.g. neurofibromas and schwannomas).^{9,24-26}

ADVANTAGES OF A THORACOSCOPIC APPROACH VERSUS AN OPEN APPROACH

Advantages of using thoracoscopy, as opposed to open thoracotomy, include smaller incision size with less pain

and fewer respiratory complications. Thoracoscopy creates a much smaller wound than open approaches. Adulkasem and Surangsrirat⁶ noted a 4-cm incision typical of thoracoscopy versus 20-cm incisions typical of traditional open approaches. Smaller chest incisions allow for quicker recovery times with shorter hospital stays, less days in the intensive care unit, and subsequently leads to reduced cost.^{6-8,11,13,14} Additionally, forced vital capacity decline may be significantly reduced in the postoperative period, when compared to open surgery.²⁷⁻²⁹ Nevertheless this is controversial, as Lenke et al.³⁰ found no statistical difference in pulmonary function after operation at 2 years in patients undergoing anterior release for adolescent idiopathic scoliosis correction. The use of small portals also avoids the need for rib resection, thus avoiding complications related to disruption of the neurovascular bundle. Small portals also minimize muscle transection, avoiding patient morbidity.³¹

Thoracoscopy has additional theoretical benefits. The video feed from the surgery is readily observed by other surgeons or trainees. Additionally, as the field of remote surgery or robotic-assisted surgery further develops, it may readily be integrated with videoscopic and thoracoscopic technologies. The ability to have a skilled spine surgeon operate on injured people at varied locations would be invaluable.³¹

Figs. 97.1A and B: T2 sagittal and axial magnetic resonance imaging showing a large central thoracic disc herniation.

DISADVANTAGES OF A THORACOSCOPIC APPROACH

Visualization during thoracoscopy may not be as good as that during open approaches where binocular vision and the use of the operating microscope are feasible. Thoracoscopy depends on television projection and many endoscopes only provide two-dimensional vision. Additionally, longer instruments, cleaning of the instrumentation (specifically bone dust from endoscopes) and a different hand eye coordination skill set than is used for open surgery may present difficulties for using this technique.⁴

PATIENT SELECTION

For thoracoscopic discectomy, Johnson et al. recommended patient selection based on the number of levels involved, the complexity of the lesion involved, the presence of ossification of the posterior longitudinal ligament and whether the patient had undergone prior transthoracic surgery. Patients with three or more disc herniations that need to be addressed, those with multisegment ossification of the posterior longitudinal ligament, and those having undergone prior transthoracic surgery may benefit from open thoracotomy over a thoracoscopic approach.⁴

For spinal deformity correction, the ideal patient for thoracoscopic approach has a curve of less than 70° with >50% flexibility or has a single structural thoracic curve or a double or triple curve where only the thoracic curve is structural.³² Liu and Kit³³ noted the optimal surgical candidate for thoracoscopic discectomy/fusion and instrumentation in scoliosis correction to be a right side thoracic,

adolescent idiopathic scoliotic curve of King 3 or Lenke type 1. They recommended that the magnitude of the structural curve should be less than 80°, thoracic kyphosis less than 40° and the weight of patient between 30 and 70 kg. They also suggested that King type 2 and Lenke type 3 and type 5 curves be considered for the procedure. Obesity and intrathoracic pleural adhesions are considered relative contraindications to the procedure.³² Thoracoscopy may also provide a minimally invasive approach to fusionless anterior scoliosis surgery in carefully selected patients with adolescent idiopathic scoliosis.³⁴

PREOPERATIVE WORK-UP

For thoracic disc herniations, magnetic resonance imaging provides useful information regarding spinal cord versus nerve root compression (Figs. 97.1A and B). Computed tomography (CT) provides detailed information regarding bony anatomy and provides more accurate information regarding calcifications in the canal and calcified disc herniations.³⁵ Patients should have preoperative lumbar and thoracic plain X-rays to assist in localization in the operating room.

THORACOSCOPIC TECHNIQUE

For the purposes of this chapter, we refer here to thoracoscopic discectomy.

Positioning and Room Setup

The patient is positioned in the lateral decubitus position, after induction of anesthesia and placement of a double

Fig. 97.2: Room setup for thoracoscopic surgery.

lumen endotracheal tube. The ipsilateral lung is collapsed, facilitating performance of the procedure while the contralateral dependent lung is ventilated. Standard neuromonitoring is used.⁴

In the lateral decubitus position, an axillary roll is used. Bony prominences and superficial nerves such as the peroneal nerve are padded and protected.³⁵ An anteroposterior (AP) radiograph is taken with markers placed on the chest wall to help determine portal position. The skin is then marked and the patient is prepped widely for possible need for thoracotomy and/or a posterior approach.^{4,35}

The surgeon and first assistant will typically stand at the abdominal side of the patient with the scrub tech at the foot of the bed. If required, a second assistant can stand at the posterior side of the patient. Video monitors should

be directly and comfortably seen by both the primary surgeon and assistants (Fig. 97.2).³⁵

Technique

Typically three endoscopic port sites are used for thoracoscopic discectomy: one is placed in the posterior axillary line and two are placed along the anterior axillary line (Fig. 97.3). Usually an endoscope is placed into the port along the posterior axillary line and instruments are used in the anterior ports. Retraction of the lung is performed and adhesions are lysed as necessary. The patient bed can be rotated to allow the lung to fall forward.

Localization can be performed by counting from the first rib and then confirmed radiographically. Usually segmental vessels are spared, but they can be retracted,

Fig. 97.3: Locations of port sites.

Fig. 97.4: Extent of bone removal.

cauterized and/or divided as necessary. The parietal pleura is dissected of the rib head and adjacent disc space using a harmonic scalpel.

A drill is used to remove the proximal 2 cm of the rib head and the lateral wall of the pedicle and the neuroforamen are exposed (Fig. 97.4). The caudal pedicle is then drilled. The posterior margin of the vertebrae is palpated and the inferior and superior endplates of the vertebrae along the disc space are burred. A trough is drilled within the vertebral body, leaving a ventral shell of bone along the spinal cord to protect the dura and cord. This may need to be deepened all the way across the contralateral pedicle depending on the size and location of pathology. The distance drilled should be verified with AP fluoroscopy. The anterior two thirds of the vertebral body should be left intact to preserve stability. Additionally, the rostrocaudal distance drilled in the vertebrae depends on the size and location of disc herniation.^{4,35} Alternatively, neuronavigation can be used to define the extent of bone removal and help localize a disc herniation.^{7,36,37}

After completion of burring, disc is removed from the disc space. The thinned out cortical floor of the spinal canal is then removed with curettes and Kerrison rongeurs. A probe or nerve hook can be used to then open the posterior longitudinal ligament and disc herniation is pulled into the trough that was previously created. This avoids manipulation of the spinal canal (Figs. 97.5A and B).

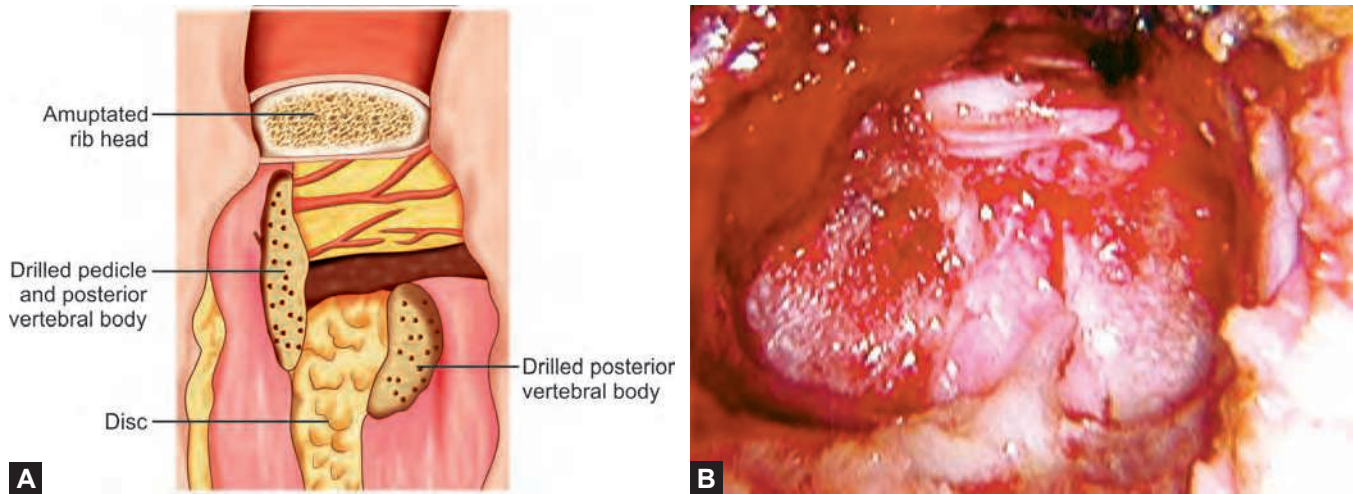

Meticulous hemostasis is then achieved. Bone grafting and fusion can then be performed in certain cases if decompression is extensive. A chest tube is placed through one

of the portals and is guided to the apex of the thoracic cavity. The lung is reinflated and the chest tube is placed to suction at 20 cm. The fascia is closed in a watertight manner and the skin is closed with buried interrupted absorbable sutures.

Typically, patients are ambulated by postoperative day 1 and chest tubes are removed by postoperative day 2 when there is less than 100 mL of drainage.^{4,35}

■ OUTCOMES OF THORACOSCOPIC SPINE SURGERY PROCEDURES

Anand and Reagan reported minimum 2-year follow-up outcomes on 100 patients who underwent video-assisted thoracoscopic discectomy.³ Forty patients underwent fusion, of whom 27 underwent rib graft placement and 13 had thread cages placed. Mean operative time was 173 minutes and mean blood loss was 259 mL. They noted an average stay of <1 day in the intensive care unit and 4 days in the hospital. They noted minor complications to occur in 21 patients, all of which resolved. There were no cases of neurologic worsening. Four patients underwent a secondary fusion, and a pseudarthrosis developed in one patient. At 2 years, 73% patients had an improvement in Oswestry score of 20% or more, which was defined as a clinical success. They concluded, "Video-assisted thoracoscopic surgery appears to be a safe and efficacious method for the treatment of refractory symptomatic thoracic disc herniations."

Figs. 97.5A and B: Decompressed spinal cord after bone, ligament and disc herniation removal.

Johnson et al. compared outcomes of 36 patients undergoing thoracoscopic discectomy with 8 patients who underwent open thoracotomy and discectomy.⁴ Lesions included soft and calcified disc herniations, Ossification of the posterior longitudinal ligament (OPLL), and discitis. They noted operative times, blood loss, and duration of chest tube drainage to be lower in patients who underwent thoracoscopy than in those who underwent open thoracotomy but were not statistically significant. Narcotic usage and hospital stay were significantly less for patients in the thoracoscopy group. Both groups largely improved neurologically. The authors concluded, "Thoracoscopic discectomy procedures have several distinct advantages over conventional procedures primarily related to reduced surgery-related pain, morbidity, length of stay, and complications. The need for adequate training and consistent surgical experience to maintain effective skills is necessary for surgeons performing thoracoscopy."

In their early landmark paper on thoracoscopic spine surgery, Newton et al.²⁹ reported 38 patients on whom endoscopic thoracic spine surgery was performed to correct idiopathic scoliosis. Approximately 5.5 hours were required to fuse an average of seven levels. The average incision length was approximately 10.5 cm. This was estimated to be one third of the length of an incision required for an open procedure. Cosmetic outcome of using this approach should not be overlooked. They used as their controls 68 patients for whom an open procedure had been performed. Deformity correction achieved was comparable to the patients for whom open procedures were performed.

Morbidity was less compared to the open procedure. The length of the surgery was longer for the thoracoscopic group, but this was felt to be a function of the learning curve for thoracoscopy.

Han et al.¹¹ reported their experience with 241 thoracoscopic procedures. These procedures include 164 thoracic sympathectomies, 60 discectomies, 5 neurogenic tumor resections, 8 corpectomies and spinal reconstructions, 2 anterior releases, and 2 biopsies. Ninety-eight percent of patients undergoing discectomies had complete decompression. They concluded this approach to be effective and to be comparable with the open procedures. They further concluded that thoracoscopy provides better visualization of the ventral spine and spinal cord than open approaches and is associated with lower morbidity rates when compared with open surgery. Furthermore, they believed that the procedure was associated with less discomfort and superior cosmesis than the traditional open approach. They also noted that thoracoscopy was faster and associated with less blood loss.

Assaker et al.⁷ reported on two patients for whom their endoscopic spine surgery was supplemented with image guidance. Patient 1 presented with a T8-T9 calcified disc and myelopathy. Patient 2 presented with lumbosacral pathology and will not be discussed further in this section. While Patient 1 did well postoperatively, the disadvantage of significant time for positioning and preparation detracted from the value of the technique. The authors postulate that with a specialized operating suite with a mobile CT scanner, the preparatory time could be significantly reduced.

Rosenthal et al.¹³ reported on their experience with herniated thoracic discs. Fifty-five patients underwent thoracoscopy. Mean surgical time was 3 hours and 25 minutes. Mean blood loss was 327 mL. When comparing thoracoscopy with costotransversectomy, they noted better resection of midline thoracic discs in the former because the thoracoscopy afforded better visualization of the anterior dura. Clinical outcomes were reported as excellent, with 22 of 36 myelopathic patients having excellent recoveries.

Huang et al.³⁸ reported on complications in 90 consecutive patients with various indications for thoracoscopic spinal surgery. The pathologies include 41 spinal metastases, 13 scoliotic patients, 12 burst fractures, 10 cases of Pott's disease, 8 cases of pyogenic spondylitis, 2 thoracic disc herniations, 2 cases of ankylosing spondylitis with diskitis, 1 osteoporotic compression fracture, and 1 case of thoracolumbar kyphosis. Thirty complications in 22 patients were noted (24.4%). Two fatalities were recorded (hemorrhage and postoperative pneumonia). Other complications noted included intercostal neuralgia, wound infection, atelectasis, pneumothorax, pharyngeal pain, subcutaneous emphysema, pericardial penetration, screw malposition, and graft dislodgement. Four patients required conversion to open thoracotomy.

Huntington et al.³⁹ used an ovine model to address the question of the ability of thoracoscopic discectomy versus open thoracic discectomy to adequately decompress the disc space. They used a total of 60 sheep in their study. After surgical intervention, the sheep were euthanized and dissected. Photographs of the vertebral end plates and remaining discs were analyzed with computer imaging. The results revealed no significant difference in the amount of disc resected, further supporting the use of an endoscopic technique.

■ RISKS OF THORACOSCOPIC PROCEDURES

As with many endoscopic approaches, the ability to broadly visualize the working field is limited by the view of the endoscope. Injury to adjacent critical structures may occur and may necessitate conversion to an open procedure.³¹ The surgeons involved may require additional training with steep learning curves. For procedures requiring image-guided navigation, there may be an increased exposure risk from radiation for patients and all operating room personnel.⁷

Cheung and Ghazi⁴⁰ reviewed complications associated with thoracoscopic approaches to the spine. They noted that complications associated with thoracoscopy are similar to those seen in open procedures with variation in the incidence of complications. These can be subclassified as complications related to anesthesia/intubation, positioning, and the use of endoscopy. Anesthetic-related complications typically were related to single lung ventilation resulting from incorrect endotracheal tube placement, wrong tube size and under or over inflation of the bronchial cuff; all these can lead to air leak into the operated lung. Other anesthetic/ventilation-related complications include air embolism and pneumothorax. Lateral decubitus positioning may lead to brachial plexus or peroneal nerve injury. Endoscopic technique may result in a vascular injury or injury to the lung parenchyma.⁴⁰ Neurologic injury may also occur, as it may with any manipulation of the spine. Endoscopic instrumentation may also break inside the chest cavity and tips of the endoscopes used may burn tissues.

Complications seen in some of the series involving thoracoscopic approaches to the spine include intercostal neuralgia, pneumothorax, pulmonary embolism, pulmonary edema, pleural effusion, atelectasis, blood loss of ≥ 2000 mL, chylothorax, implant failure (where a fusion occurred), pneumonia, and ileus.^{3,12,41-43}

■ COMPLICATION AVOIDANCE

Patients considered for thoracoscopy, and thoracotomy, should be screened for pre-existing pulmonary disease. Smokers should be urged to stop smoking preoperatively. If patients with pre-existing pulmonary disease are to be scheduled for surgery, pulmonary medicine consultation should be obtained.

Ample padding should be provided during positioning in order to avoid superficial nerve palsies. We also recommend placement of an axillary roll to minimize the risk of axillary nerve injury.³⁵

In terms of the ventilated lung, positive end expiratory pressure while continuous positive airway pressure on the nonventilated lung can minimize risk of respiratory depression and atelectasis. Improper placement of the endotracheal tube may result in decreased arterial oxygen saturation or failure to collapse the lung on the operated side; after positioning the patient in the lateral decubitus position, the double lumen tube's position should be rechecked with bronchoscopy. If insufflation is used to collapse the lung, pressures should be kept below 10–15 mm Hg to minimize the risk of compression of the mediastinum and cardiac tamponade.⁴⁰

Placement of thoracoscopic ports can result in bleeding and in pulmonary injury. The first port placed is always done blindly: placement should be done as gently as possible while avoiding disruption of the neurovascular bundle that runs beneath the ribs. Subsequent ports should be placed under thoracoscopic visualization. Prior to port placement, adhesions may need to be dissected. This can be done bluntly with the surgeon's gloved finger.⁴⁰

Use of soft thoracoscopic ports has been recommended, as they are associated with a reduced incidence of intercostal neuralgia. Stiff portals, however, may more readily allow introduction of instruments into the chest cavity.³⁵

Careful visualization of instruments introduced into the thoracic cavity must occur at all times. This is particularly true regarding fan retractors, dissectors, drills, and any other instruments used around the spinal cord. Bleeding should be kept to a minimum. Any bleeding edges of bone should be waxed. Additionally, bipolar electrocautery and hemostatic clips can be used. If segmental vessels are going to be ligated, they should be ligated close to their origins to minimize the risk of spinal cord infarction. Monopolar cautery should be avoided, especially around the head of the rib, as this may contribute to intercostal neuralgia.^{4,35,40}

If a durotomy is encountered during discectomy, this can theoretically be repaired with a fine suture or patched with fascia. If a leak cannot be repaired, we recommend cerebrospinal fluid diversion with a lumbar drain and placement of the chest tube to water seal drainage to minimize risk of cerebrospinal fluid-pleural fistula.³⁵

All patients should be mobilized as early postoperatively as possible and also be treated with aggressive pulmonary toilet to help reduce the risk of atelectasis, pneumonia, and deep venous thrombosis, among other complications.

CONCLUSION

Thoracoscopic discectomy is a less invasive means of achieving anterior decompression of the thoracic spinal canal. Variations of the technique have been used for treatments of numerous spinal disorders. Careful patient selection, meticulous technique, knowledge of perioperative care and complications, and frequent practice are required for good outcomes.

INTRODUCTION

Thoracic discectomy and corpectomy are the two major procedures indicated in the surgical management of thoracic spinal disease. Thoracic disc disease, which is much less common than its lumbar counterpart, is typically treated conservatively. When conservative management fails and symptoms persist, or if myelopathy is present, thoracic discectomy is indicated to decompress the thoracic spinal cord and affected nerve roots. Thoracic corpectomy is reserved for certain thoracic burst fractures, tumors, infections, severe deformity, and spinal instability. This chapter describes thoracic disc disease, thoracic discectomy, and thoracic corpectomy.

THORACIC DISC DISEASE

Epidemiology

The actual prevalence and incidence of thoracic disc herniation is unknown, as the majority is either unrecognized or asymptomatic. Most patients are in their fourth to sixth decades of life and there is a slight male predilection.¹⁻⁴ Symptomatic women tend to present at a later age than men.⁵ A small number of adolescents with Scheuermann's disease present with a progressive neurologic deficit secondary to an acute thoracic disc herniation. Between 33% and 50% of patients report a history of trauma or significant physical exertion prior to the onset of symptoms.^{5,6}

In 1995, Wood et al.⁷ evaluated magnetic resonance imagings (MRIs) of from 90 asymptomatic individuals and found thoracic disc abnormalities in 73%. Of these subjects, 37% had frank disc herniation and 29% showed definite cord deformation. In a later study, 20 patients with 48 asymptomatic thoracic disc herniations previously diagnosed on MRI were re-examined.⁸ No patient became symptomatic during the study period, with a mean follow-up interval of 26 months. They also noted that small herniations either remained unchanged or increased in size, while larger herniations tended to get smaller over time. The authors concluded that asymptomatic thoracic disc herniations exhibit relatively little change in size over time and rarely become symptomatic. Numerous other authors have conducted epidemiologic studies of thoracic disc herniation.^{9,10} Most recently, Niemelainen et al.¹¹ reported that degenerative thoracic MRI changes were less common than previously reported. The authors found anterior disc bulging in 45.2% of asymptomatic patients, ages 35–70, and posterior disc bulging in 9.2% of subjects (Fig. 98.1).

Surgical treatment for thoracic disc herniation is rare and only accounts for between 0.15% and 4% of all disc operations.¹²⁻¹⁸ Historically, treatment of this disorder has been problematic. This is partly related to the infrequency of the disease. Furthermore, indications for surgery are not well established because the natural history of the disorder is not clearly defined. In general, the presence of severe or

Fig. 98.1: Sagittal magnetic resonance imaging of thoracic disc herniation.

progressive myelopathy is regarded as an absolute indication for surgery.¹⁸ The role of surgery as a means to control pain is controversial; it has been reported that radicular pain responds better to surgery than does nonradiating, axial thoracic pain.^{19,20}

Etiology

The majority of authors favor degenerative processes as the major cause of thoracic disc herniation.^{1,12,21} This is supported by the finding of higher incidence of disc herniation in the lumbar spine, where greater degenerative changes are noted. In their cross-sectional study of men 35–70 years of age in the Finnish Twin Cohort, Niemelmainen et al.¹¹ noted moderate-to-severe thoracic disc height narrowing in 21.4% of the subjects.

Although the role of degeneration in the etiology of thoracic disc disease is well accepted, the role of trauma as a cause of herniated thoracic discs remains controversial. A history of trauma can only be elicited in 14–63% of patients with a thoracic disc herniation.^{3,22} The degree of reported trauma responsible for the herniation is also quite variable, ranging from minor twisting mechanisms to major falls or motor vehicle accidents.²³

Finally, Scheuermann's disease has been implicated as a potential causative process for thoracic disc disease. Numerous authors have postulated an association between the primary pathologic process of the disease or secondary degeneration due to the disease resulting in increased incidence of disc herniation.^{24–27}

Clinical Presentation and Diagnosis

The differential diagnosis of thoracic pain is variable and includes both spinal and nonspinal pathologies. Although not exhaustive, Vanichkachorn et al.⁵ presented a comprehensive list of both nonspinal and spinal causes that should be considered in patients presenting with thoracic pain. Nonspinal causes can include intrathoracic (cardiovascular, pulmonary, and mediastinal), intra-abdominal (hepatobiliary, gastrointestinal, retroperitoneal), and musculoskeletal (post-thoracotomy syndrome, polymyalgia rheumatic, fibromyalgia, rib fractures) pathologies. Spinal causes include infectious, neoplastic, degenerative, metabolic (osteoporosis, osteomalacia), deformity (kyphosis, scoliosis, trauma), and neurogenic etiologies.

Although there is extreme variation in the clinical presentation of patients who have a herniated thoracic disc, they can generally be divided into three groups depending on the symptoms at presentation: predominantly axial pain, radicular pain, or thoracic myelopathy.⁵ Arce et al.¹² characterized the patterns of typical initial presentation for thoracic disc herniation: 57% described pain, 24% described sensory disturbance, 17% described motor weakness, and 2% described bladder dysfunction.

Pain, whether axial or radicular, is the most common presenting complaint for patients with a symptomatic thoracic disc herniation. Axial pain is usually localized to the middle to lower thoracic region; however, in some circumstances, it may have a radiating component referred to the middle to lower lumbar spine. The pain is generally characterized as mild to moderate in intensity.⁵

Thoracic radiculopathy is often described as pain in a band-like distribution following a discrete dermatome. The T10 dermatomal level is the most commonly reported distribution regardless of the involved level. Radicular pain is typically accompanied by axial pain. Sensory changes including paresthesia and dysesthesia are the second most commonly reported symptoms of acute thoracic disc herniation.

The most urgent and worrisome presentation of thoracic disc herniation is myelopathy. Weakness and upper motor neuron signs including clonus, gait disturbances, and spasticity can indicate thoracic cord compression. Concurrent cervical disease should also be suspected and investigated in these patients. However, patients with thoracic myelopathy without cervical myelopathy may present with upper motor neuron signs in the lower extremity, without upper extremity complaints.

In addition to a thorough physical examination to confirm a spinal etiology, a clinician must evaluate the entire spine to differentiate between the cervical, thoracic, and lumbar spine as a source of the patient's symptoms. Advanced imaging modalities are critical to confirm suspected diagnoses from the clinical exam, and include plain radiographs (including flexion and extension views), computed tomography (including myelography when indicated), and MRI.

Nonoperative Management

Because the vast majority of patients present with pain without myelopathy, the natural history of most acute thoracic disc herniation is benign and mimics the course of herniation in the lumbar spine. The management of acute thoracic disc herniation is, therefore, similar to nonoperative management protocols for patients with acute lumbar herniation.⁵

In the acute phase, activity modifications, anti-inflammatory drugs, and physical therapy are the conservative modalities of choice. Brown et al.²⁸ reported successful nonoperative treatment of 63% of patients with a symptomatic disc herniation. Additional nonoperative interventions include intercostal nerve injections and, occasionally, bracing, although little literature exists proving the efficacy of these treatments.

THORACIC DISCECTOMY

Indications and Contraindications

Surgical treatment for thoracic disc herniation is rare and only accounts for between 0.15% and 4% of all disc operations.¹²⁻¹⁸ Thoracic discectomy is indicated for the minority of patients. In patients with an acute disc herniation with myelopathic findings attributable to the lesion, especially if there is progressive neurologic deterioration, discectomy may be indicated. In addition, selected patients with persistent and intolerable pain who have failed conservative measures may be considered for thoracic discectomy.

Surgical Approach

Selection of the optimal surgical approach for discectomy is controversial. Historically, patients treated with laminectomy alone resulted in suboptimal outcomes, likely related to the ventral force placed on the spinal cord by the herniated disc that is inadequately reduced by removing

only the lamina.^{17,18,20,29,30} When discectomy was performed via laminectomy, spinal cord manipulation was often not well tolerated, due to the limited space available for the spinal cord in the thoracic spine and its tenuous blood supply.^{14,28-31}

Surgical approaches that avoid these issues can be grouped into anterior approaches, including transthoracic; posterior approaches including laminectomy and pediculofacetectomy; and lateral approaches, including costotransversectomy and lateral extracavitary exposure. The actual approaches are discussed in a previous chapter, as are their advantages and disadvantages, which must be carefully considered when selecting the method of exposure.⁵ In this section, we will focus on the actual discectomy accomplished once the surgical approach is complete.

Anterior Approaches

The transthoracic approach is the most commonly used anterior approach to the thoracic spine. Advantages to this approach include a more direct approach to the disc and better visualization, facilitating excision of a central herniation and a herniation with intradural penetration. Few complications have been described after thoracotomy for discectomy.^{12,22,32-36}

The patient is placed in the lateral decubitus position. In general, lateral prolapse is best approached from the ipsilateral side; a midline herniation may be approached from either side. The right side has the advantage of avoiding the great vessels and the heart in the upper and middle thoracic spine, and a statistically lower risk to the artery of Adamkiewicz because it is located on the left in approximately 80% of patients.^{37,38} After the approach is complete, the recommended extent of bone and disc removal varies from a small amount in the posterior aspect of the disc to complete discectomy with partial corpectomy of the adjacent bodies.^{22,32,34,35} Partial corpectomy provides the greatest degree of visualization and allows for more complete discectomy (Figs. 98.2A and B).

Posterior Approaches

The posterior approach to the thoracic spine is the workhorse approach for many spinal conditions. However, as detailed earlier in the chapter, decompressive laminectomy from a midline approach for thoracic discectomy is largely historical. Frequent morbidity associated with posterior laminectomy for thoracic discectomy—including neural

Figs. 98.2A and B: Schematic photographs demonstrating the transthoracic approach to the thoracic spine.

injury, inadequate decompression, and continued symptoms—has led to the abandonment of this technique.⁵ Arce et al.⁴ reviewed 135 patients after laminectomy for thoracic discectomy, and found that only 58% improved, 10% were unchanged, 28% were made worse, and 4% died.

As a result, more specifically for thoracic disc disease, decompressive laminectomy and thoracic discectomy through a posterior transpedicular, posterolateral extracavitary, or costotransversectomy approach may avoid many of these complications. However, it should be noted that these approaches are frequently destabilizing and typically performed along with a spinal fusion and stabilization with instrumentation.

Transpedicular Approach

The transpedicular approach in thoracic decompression was first described in 1978 and is used mainly to decompress associated nerve roots in soft disc herniations.^{39–42} The details of this surgical approach are discussed in a previous chapter. This technique is best suited for the removal of lateral and some soft paramedian disc herniations in the upper thoracic spine and is aided by the use of the operating microscope.

The appropriate level is determined and the thoracic pedicle overlying the disc herniation is identified. The superior and inferior facets are often removed to allow better exposure of the intended pedicle. The central portion of the pedicle is then removed with a high-speed bur. The medial and superior cortical bone is removed, maintaining the lateral and inferior portions of the pedicle.

Disc material is then removed through this opening, taking care not to injure the cord or nerve roots during this process. Performing a laminectomy before this stage allows for clear identification of the exiting nerve root. Le Roux et al.¹⁹ reported on 20 patients with thoracic disc herniation treated through a transpedicular approach. At the 1-year follow-up, 100% had significant improvement and 40% had no reportable symptoms. Levi et al.⁴³ reported similar good results with the approach. Concerns of instability caused by this approach led to the development of a transfacet pedicle-sparing approach.¹⁷

Posterolateral Approaches

The two most commonly used posterolateral surgical exposures for thoracic discectomy are the lateral extracavitary and costotransversectomy approaches. The lateral extracavitary approach is a modification of the lateral thoracotomy approach described by Larson for use in treating spine disorders.^{5,44} Again, the details of the approach are discussed in a prior chapter. Once the surgeon has resected the rib and the transverse process is removed, the neurovascular bundle can be followed to the neuroforamen. The pedicle is taken down. After the transverse process and pedicle have been removed, discectomy can be performed. If additional exposure is needed to obtain additional discectomy, the vertebral body can be decompressed, making sure to leave a rim of cortical bone just ventral to the thecal sac to protect the spinal cord.

Costotransversectomy, first used in 1900 by Menard for the drainage of a thoracic tubercular abscess, can be

performed in either a prone position or with a classic posterolateral approach. Details of the approach can be found in a prior chapter. This approach does not violate the pleura and is very useful in the removal of paramedian and lateral disc herniations in the entire thoracic spine.⁵ It is not generally the desirable approach when a complete anterior decompression is needed in a case of advanced myelopathy.

Minimally Invasive Techniques

As technology has progressed, spine surgeons have used smaller incisions and found minimally invasive techniques for simple discectomy or decompression of individual nerve roots. Thoracoscopy has the potential advantage of avoiding the pulmonary complications and morbidities of an open thoracotomy. Regan et al. first reported the use of thoracoscopy for the treatment of spinal disease, using the technique to biopsy and drain a thoracic paravertebral abscess.⁴⁵ In the past 5 years, numerous minimally invasive techniques have been described for thoracic discectomy, including advances in thoracoscopy, use of endoscopy, and tube-assisted approaches among others.^{35,42,46-60}

THORACIC CORPECTOMY

Indications

The indications for thoracic corpectomy include burst fractures, tumors, infections, severe deformity, and spinal instability.

Infection

The actual mechanism for spinal infections remains controversial; evidence exists to support both arterial and venous hematogenous spread, local extension from nearby infections, and direct inoculation. Authors who support an arterial mechanism of spread note that the region near the anterior longitudinal ligament is an area where infections typically begin, which has an arteriole network that is susceptible to bacterial seeding.⁶¹ Advocates of venous hematogenous spread argue that organisms are carried to the spine via the plexus of Batson, similar to tumor metastases.⁶²

Trauma

Unlike the cervical and lumbar spine, the thoracic spine is stabilized by the vertebral column, and receives additional

stability from the surrounding ribs and sternum. Anatomically, this has been described as the “fourth column” and Shen and colleagues have shown it to be a clinically significant entity. As a result, typically the thoracic spine requires high-energy injury to produce instability or significant fracture. Although most injuries do not involve significant neurologic deficit, when deficit does occur, complete deficits are more common in the thoracic spine due to the small neural canal and tenuous blood supply.^{63,64} If operative treatment is required, typically, decompression involves corpectomy to provide adequate exposure and decompression of the spinal cord.

Tumor

Metastatic disease to the spine has become increasingly prevalent with better treatment and longer patient survival. It is estimated that between 5% and 33% of all patients with systemic malignancy will have spinal involvement.⁶⁵⁻⁶⁷ Over 90% of spinal tumors are metastatic lesions with a distant primary source. Primary sources include the breast, prostate, lung, kidney, and thyroid.⁶⁸ The primary concerns when treating spinal metastases are: preservation of neural function, maintenance of mechanical stability, and minimization of overall morbidity. Treatment should be designed to maximize meaningful survival outside of the acute care setting.⁶⁹

Operative Treatment

Thoracic corpectomy can be accomplished through an anterior approach, costotransversectomy, thoracic transpedicular approach, or a variety of newer minimally invasive approaches. Although these approaches are discussed in detail in previous chapters, it is worthwhile to note here that, in the thoracic spine, although the T1 nerve root should be preserved whenever possible, in some cases, it may be necessary to perform a rhizotomy of the one of more of the remaining thoracic roots.

Corpectomy

Once the vertebral body is identified in the surgical approach, discectomy is performed both above and below the level of corpectomy. This is accomplished by incising the annulus, elevating the disc to separate it from the endplates, and then completing the discectomy using curettes and rongeurs. The corpectomy is started using a burr and completed by removing the remaining bone with a rongeur. Depending

Figs. 98.3A to C: Sagittal plain X-ray (A), computed tomography scan (B), and magnetic resonance imaging (C) of an 85-year-old woman with 5 weeks of mid-thoracic back pain after a ground-level fall. The patient sustained T6–T8 compression fractures with a significant kyphotic deformity.

Figs. 98.4A and B: The patient described in figure 98.2 was initially managed conservatively; however, she began to develop neurologic deterioration with myelopathy. She underwent T7 and T8 corpectomies with interbody cage placement and instrumented fusion from T4 to T11. She had remarkable improvement in neurologic function postoperatively.

on the pathology, the posterior longitudinal ligament (PLL) may need to be removed for the purposes of decompression. For traumatically retropulsed fracture fragments, care is taken to peel the fragments away from the dura. Once the corpectomy is completed, plating or screw/rod constructs

can be used to stabilize the segment through the same approach. Either bone grafting and cage or allograft is used in place of the removed vertebral segment (Figs. 98.3 and 98.4).

Special Considerations

It is generally considered safe to place an allograft, bone graft and cage, or instrumentation in the setting of anterior spinal infection if a thorough debridement is performed and appropriate postoperative antibiotics are given.^{70,71} Anterior column reconstruction with polymethylmethacrylate is generally reserved for tumor reconstructions in patients with a life expectancy of <1 year, or in patients in whom radiation or chemotherapy is planned.

COMPLICATIONS

Fessler et al.⁷² reviewed the rates of morbidity and mortality as well as complications related to thoracic discectomy, and found similar rates between various surgical approaches if laminectomy was excluded. The surgery-related complications of paralysis and significant paresis have become relatively rare since laminectomy was abandoned, with only five recent cases of postoperative neurologic deterioration reported.^{6,22,73} Continued symptoms after thoracic discectomy are a concern, and has been

reported by several authors.⁷⁴ Bohlman et al.²² reported one misidentified disc level in their series.

Symptomatic spinal instability is another concern following thoracic discectomy and, although uncommon, has been noted by several authors postoperatively.^{18,75} The incidence of cerebrospinal fluid leakage has been reported from 0% to 15% in a published series.⁷⁴ Lung-related complications, including atelectasis, pneumonia, and pulmonary embolism have been reported, but are not associated with any particular approach.^{18,30,70,75-77} Pleural tears are not a true complication, as all transthoracic discectomies involve pleural disruption. During extracavitary approaches, unintentional pleural tears have been reported.³⁰ Infection rates from 0% to 18% have been reported.^{18,30,31,77} Rare complications including postoperative cerebrovascular accidents, incisional hernia, lateral femoral cutaneous nerve injury, and transient paraplegia have all been reported, but are not commonly associated with these procedures.^{6,72,76}

KEY POINTS⁵

- Thoracic disc disease is not nearly as common as lumbar disc disease, but affects persons more commonly in their fourth to sixth decades
- Although the typical management of thoracic disc disease is conservative, thoracic discectomy is an option when nonoperative interventions fail
- Thoracic discectomy is preferable to laminectomy alone, and can be accomplished through anterior, lateral, or posterior approaches with reasonable success, depending on the location within the thoracic spine and the location of the disc herniation
- Thoracic corpectomy is indicated for certain burst fractures, tumors, infections, severe deformity, and spinal instability
- Complications of thoracic discectomy and corpectomy are infrequent since the abandonment of laminectomy, and include infection, lung complications, and persistent symptoms.

- » Clinical Utility

BACKGROUND

History

In modern spine surgery, surgeons regularly utilize thoracic pedicle screws in order to achieve segmental fixation in the surgical treatment of conditions such as deformity, tumor, trauma, infection, and degeneration. The use of instrumentation in the thoracic spine began with Harrington distraction rods in the 1960s and advanced to Luque wires and Cotrel–Dubousset hooks and screws in order to achieve segmental control of the thoracic spine.¹ Introduced by Boucher² and popularized by Roy–Camille et al.,³ lumbar pedicle screws were being used regularly by the 1980s. Around this time, spine surgeons were expanding the use of pedicle screws to the thoracic spine; however, many were careful to note the technical difficulty and risks associated with placing pedicle screws in the thoracic spine^{4,5} compared to the lumbar spine. With the advent of more modern techniques, spine surgeons began using thoracic pedicle screws on a more regular basis.^{6,7} Today, thoracic pedicle screws have become the gold standard for segmental fixation of the thoracic spine.

Advantages

There are several advantages to the use of pedicle screws versus hooks or sublaminar wires for thoracic spine fixation. Thoracic pedicle screws allow for three-column fixation and hence allow for greater control of the thoracic

spinal segment. In a biomechanical analysis, Hackenberg et al.⁸ demonstrated greater fixation strength in pedicle screws versus supra-laminar/pedicle hooks in a thoracic cadaveric model. While some studies have demonstrated no significant differences in curve correction,⁹ many studies have demonstrated that the improved fixation strength associated with thoracic pedicle screws allows for greater correction and improved maintenance of correction in deformity surgery. Kim et al.¹⁰ performed a matched, retrospective cohort examination of pedicle screw versus hook constructs for patients with adolescent idiopathic scoliosis at a large deformity center. They demonstrated significantly improved major and minor curve correction, better maintenance of correction at 2 years, improved pulmonary function, and saved an average of 0.8 levels at the distal end of the construct in the pedicle screw cohort.¹⁰ The same group performed a similar analysis comparing pedicle screw and hybrid constructs. Again, they demonstrated significantly improved major and minor curve correction, maintenance of correction at 2 years, and improved pulmonary function in the pedicle screw cohorts.¹¹ Other investigators have also shown similar results in adult deformity patients.^{12–14} Rose et al.¹³ performed a matched, retrospective cohort analysis of adult idiopathic scoliosis patients and demonstrated better curve correction and maintenance of thoracic kyphosis in the pedicle screw cohort compared to the hook/hybrid cohort. Yilmaz et al.¹⁴ compared hook, hybrid, and pedicle screw constructs in a retrospective analysis and showed significantly

better curve correction in the patients treated with pedicle screws. Pedicle screws have also proven to provide greater curve correction for more severe curves greater than 80°. ¹²

The greater biomechanical fixation offered by thoracic pedicle screws has allowed for improved curve correction without disrupting the rib cage through open anterior thoracic approaches. Koptan et al. ¹⁵ showed similar kyphosis correction in Scheuermann's kyphosis patients who underwent all-posterior pedicle screw constructs versus staged anterior/posterior procedures. In another study, Rose et al. ¹³ found that patients with all pedicle screw constructs required less anterior release in order to achieve curve correction in adult idiopathic scoliosis patients. Other investigators have demonstrated superiority of all pedicle screw versus anterior dual-rod constructs for Lenke 5C curves, ¹⁶ and similar results between anterior/posterior approaches and pedicle screw/posterior-only approaches in severe Lenke 1 and 2 curves. ¹⁷ Achieving deformity correction without disrupting the chest cage is important because it has been shown to negatively impact postoperative pulmonary function in adolescent idiopathic scoliosis patients. ¹⁸

Historically, axial derotation in order to correct thoracic prominence in deformity surgery has been difficult to achieve using hook/sublaminar wire constructs. ^{19,20} This difficulty has been mitigated to a certain extent with the fixation strength afforded by thoracic pedicle screws. A recent biomechanical study demonstrated that the rotational control on the thoracic spine increases linearly with each additional linked pedicle screw. ²¹ The rotational control provided by thoracic pedicle screws has been instrumental in the development of direct vertebral rotation and rod de-rotation techniques for reducing the thoracic prominence/rib hump deformity. ^{22,23}

Disadvantages

The drawbacks associated with the use of thoracic pedicle screws include: steep learning curve, proximal junctional kyphosis (PJK), possible increase in operating time, neurologic complications, vascular complications, and cost. Several studies have examined the learning curve associated with placing pedicle screws. ²⁴⁻²⁸ One of the largest studies analyzed 96 consecutive patients with Lenke 1 curves who were treated with thoracic pedicle screw constructs. With an increase in case number over the course of the study, the authors noted decreased blood loss, decreased time per screw, increased implant density, and decreased total

operative time. ²⁵ The steep learning curve associated with the use of thoracic pedicle screws has also been illustrated in other studies looking at residents of different levels ²⁴ and senior surgeons. ^{26,27} In a more recent study, Gang et al. ²⁸ investigated the learning curve of apprentice surgeons using a retrospective cohort analysis. They showed that apprentice surgeons were ready to independently insert thoracic pedicle screws after placing 60 thoracic pedicle screws under the supervision of the chief surgeon. This data clearly demonstrates a steep learning curve for placing thoracic pedicle screws, especially in deformity surgery.

It is clear that thoracic pedicle screws have increased fixation of the thoracic spinal segment; however, it is not clear if this greater fixation leads to a higher risk of PJK. Some investigators have noted a greater decrease in thoracic kyphosis with increasing pedicle screw density ²⁵ or with all posterior pedicle screw constructs versus all anterior dual rod fixation. ²⁹ Many have postulated that this decrease in thoracic kyphosis predisposes to PJK. This may be especially worrisome in adult scoliosis patients who may have osteopenia and other risk factors that could lead to catastrophic failure at the proximal end of the construct. ³⁰ Kim et al. ³¹ examined the incidence and risk factors of PJK in adolescent idiopathic scoliosis patients treated with three different posterior constructs. There was a significantly higher incidence of PJK in the patients treated with all pedicle screws versus hooks, but no significant difference between the hybrid and pedicle screw cohorts. The authors also noted the following risk factors for PJK postoperatively: larger preoperative thoracic kyphosis, greater decrease in thoracic kyphosis postoperatively, thoracoplasty, and male gender. ³¹

Other disadvantages of thoracic pedicle screws are increased operative time, cost, and neurologic/vascular complications. Some purport that placement of thoracic pedicle screws increases overall operative time because of the technical difficulty associated with screw placement. Although more operative time for lengthy procedures is an important consideration, most studies demonstrating an increased operative time were performed during early experience and were not compared to nonpedicle screw cohorts. ²⁵ Other studies directly comparing different instrumentation with pedicle screws have shown no significant difference in total operative time. ^{10,11} It should be noted, however, that these studies were performed at large deformity centers where thoracic pedicle screws were used on a regular basis. The effect of pedicle screw instrumentation on operative time is invariably linked to the learning curve associated with their placement.

The implant costs associated with pedicle screws is higher than older implants, such as hooks or wires.^{9,10} Most studies have demonstrated greater curve correction using pedicle screw constructs, but the postoperative subjective outcomes in deformity patients have not proven to be significantly different.^{10-12,14} Moreover, similar results have been observed when comparing a higher versus lower number of pedicle screws in adolescent idiopathic scoliosis.³² More research must elucidate the most efficacious, yet cost-effective use of instrumentation. This is vital given the findings of a recent study that demonstrated instrumentation to be 29% of the overall costs associated with scoliosis surgery, estimated to be US\$ 29,955–\$60,754 depending on the curve type.³³

Radiation exposure to the surgeon and operating room staff is also a disadvantage in the use of thoracic pedicle screws. The extent of radiation exposure is dependent on the technique used for screw placement. One study outfitted the surgeon with a thermoluminescent dosimeter to estimate radiation exposure to his whole body and thyroid gland during fluoroscopically guided pedicle screw placement.³⁴ This study suggested that the radiation exposure recorded in this study would lead to the upper limit of recommended lifetime radiation exposure after 10 years. Efforts to decrease this exposure would be beneficial for both the surgeon and the operating room (OR) staff. Other disadvantages related to thoracic pedicle screws include the neurologic and vascular complications ranging from minor nerve root irritation to spinal cord or the great vessel injury. These complications are discussed later in this chapter.

There are advantages and disadvantages associated with the use of pedicle screws in thoracic spine surgery. They are not only used most commonly in deformity surgery, but also can be useful for surgical treatment of degenerative conditions, trauma, tumor, and infection. With careful use, thoracic pedicle screws can allow for excellent fixation, but spine surgeons should be aware of the learning curve and technical issues related to placing pedicle screws in order to minimize complications and maximize outcomes.

ANATOMY

Techniques of Thoracic Pedicle Screw Placement

Surgeons utilize multiple different techniques for placement of thoracic pedicle screws. Originally, the freehand techniques for placing lumbar pedicle screws described by

Roy-Camille et al.³ were extrapolated to the thoracic spine and used extensively by surgeons.⁴ Over time, others have refined these techniques using greater knowledge of the detailed anatomy of the thoracic spine.

Today, the most popular freehand technique was described and popularized by Kim et al.³⁵ After subperiosteal exposure of the posterior thoracic spine out to the tips of the transverse processes, the inferior 3–5 mm of the inferior articular facets are removed using an osteotome. The starting point is then identified according to the level (Figs. 99.1 and 99.2; Kim et al. 2004). We should emphasize that the starting points and trajectories described here are specific to the straightforward thoracic pedicle screw insertion technique. The distal-most thoracic starting point at T12 is the junction of the bisected transverse process and lamina, just medial to the lateral edge of the pars interarticularis. Moving to more proximal levels, the starting point moves cephalad and medial until it reaches the most medial starting points at T7–9, which are at the junction of the superior edge of the transverse process and just lateral to the midpoint at the base of the superior articular process. More proximal to T7, the starting point becomes more lateral and caudad. At T1, the starting point is located at the junction of the bisected transverse process and lamina at the lateral border of the pars interarticularis. No thoracic pedicle screw starting point is medial to the midpoint of the superior articular process (superior articular process rule). Following the starting point identification, a burr is used to start the pedicle path to a depth of 5 mm. The 2-mm thoracic pedicle gearshift is pointed laterally and advanced into the pedicle with firm pressure to 20 mm—the typical length of the pedicle isthmus. Then, the gearshift is removed, turned 180°, and advanced into the vertebral body. Any sudden advance of the gearshift should be investigated with a ball-tipped pedicle sound. In the case of a successful thoracic gearshift pass, the surgeon should confirm the presence of a floor and four walls within the pedicle. The pedicle is then typically tapped 0.5–1.0 mm less than the diameter of the intended screw. Following placement of the screw, the surgeon can then confirm intraosseous screw placement by using fluoroscopy and/or triggered electromyography, depending on surgeon preference.³⁵

Alternatives to the freehand technique generally involve either fluoroscopy or computed-tomography (CT) navigation. Fluoroscopy-guided techniques use multiplanar imaging in order to determine the starting point using either an open or percutaneous technique. The

The text boxes indicate the trends related to the starting points. *Source:* Adapted from Kim YJ, Lenke LG, Bridwell KH, et al. Free hand pedicle screw placement in the thoracic spine: is it safe? *Spine (Phila Pa 1976)*. 2004;29(3):333-42.³⁵

Figs. 99.2A and B: Transverse cuts of a computed tomography scan at the level of a pedicle in the thoracic spine demonstrate the trajectory and relative width (a) of the thoracic pedicle (A) versus the width (b) of the pedicle/rib head complex (B).

Source: Adapted from O'Brien MF, Lenke LG, Mardjetko S, et al. Pedicle morphology in thoracic adolescent idiopathic scoliosis: is pedicle fixation an anatomically viable technique? *Spine (Phila Pa 1976)*. 2000;25(18):2285-93.⁴⁵

starting hole is then created and a thoracic pedicle gear-shift is advanced using intermittent images. After the pedicle screw path is created and confirmed fluoroscopically, the pedicle is tapped and a screw is placed.³⁶ In

recent years, CT-navigated pedicle screw placement has emerged and continues to gain popularity. This technique involves intraoperative CT after the patient is positioned followed by computer-generated guidance on the appropriate starting point, angle, and placement. CT scans can also be used in order to generate a three-dimensional (3D) computer-generated model preoperatively that is used in conjunction with the patient's anatomy in order to identify ideal starting points.³⁷

When placing thoracic pedicle screws, the trajectory of the screw is just as important as the proper starting point. In the transverse plane, the T1 thoracic pedicle is medially angled 28.2°; this decreases progressively to 8.2° at T12.³⁸ In the sagittal plane, the thoracic pedicles are angled downward the most at T2, 18.9°, and this decreases gradually as one proceeds caudad, to 10.7° at T12.³⁸ The intended path of the pedicle screw is also a point of debate. Many surgeons prefer to use the straightforward technique in which the pedicle screw is angled straight into the vertebral body just under the superior endplate, whereas others prefer the anatomic technique in which the pedicle screw is inserted parallel to the orientation of the thoracic pedicle.³⁹ Lehman et al.⁴⁰ demonstrated significantly higher maximal insertional torque and pullout strength in straightforward versus anatomic thoracic pedicle screws. Future research must elucidate the best thoracic pedicle screw trajectory.

Once a thoracic pedicle screw is placed, confirming accurate screw placement is generally recommended using fluoroscopy and/or triggered electromyography (EMG). Fluoroscopy is a common method to confirm screw placement but has limitations, especially in deformity where obtaining images orthogonal to the plane of the spine can be difficult. Upper thoracic pedicle anatomy can also be particularly difficult to visualize well using fluoroscopy, given the proximity of the shoulders. Triggered EMG is also frequently employed to test pedicle screws after placement. If the pedicle has a breach, the current will be transmitted through the pedicle screw to the nerve root at low amplitudes. One group uses triggered EMG values <6.0 mA as an indication that the pedicle screw may have a medial breach.³⁵ Other investigators have suggested different thresholds in deformity surgery. de Blas et al.⁴¹ demonstrated that different thresholds for triggered EMG should be used on the concavity versus the convexity in thoracic pedicle screws placed for deformity because of the displacement of the spinal cord toward the concavity of the spine. On the concavity, triggered EMG values of < 8.0 mA were an indication of medial breach whereas values > 14 mA indicated an intraosseous screw. On the convexity, triggered EMG values < 11 mA indicated a medial breach whereas values > 19 mA confirmed an intraosseous screw. Despite these findings, the authors concluded that triggered EMG has low sensitivity for detecting pedicle screws with a medial breach.⁴¹ The utility of triggered EMG is especially difficult proximal to T6 because of the problems associated with measuring EMG activity in the intercostal muscles versus the rectus abdominus.^{35,42}

The technique used for thoracic pedicle screw placement is at the discretion of the surgeon. The costs as well as time associated with using intraoperative CT navigation techniques have limited its widespread use. The authors prefer to use the freehand technique, as described by Kim et al.³⁵

Thoracic Pedicle Anatomy

Because of the increased use of thoracic pedicle screws, many researchers have conducted investigations of the detailed anatomy of thoracic pedicles. Kothe et al.⁴³ performed a cadaveric study in which they demonstrated that the medial pedicle wall is 2–3 times thicker than the lateral wall. Furthermore, they showed that the cancellous channel is approximately two-thirds of the outer pedicle height and width. Ugur et al.⁴⁴ did an extensive analysis of the

thoracic pedicle dimensions, nerve root dimensions, and nerve root exit angle. Because of significant variation in thoracic pedicle size, they recommended detailed analysis of a CT scan preoperatively before placing thoracic pedicle screws.⁴⁴ In another thoracic pedicle anatomic study, O'Brien et al.⁴⁵ noted the significantly increased width of the thoracic pedicle/rib head complex (12.6–17.9 mm) compared to the thoracic pedicle width (4.6–8.25 mm). The authors noted that, in thoracic pedicles with severely narrowed pedicular width, an in-out-in technique could be utilized for thoracic fixation whereby the pedicle screw can start in the pedicle, pass laterally at the pedicle/vertebral body junction, and then insert back into the lateral vertebral body (Figs. 99.2 and 99.3, from Obrien 2000).⁴⁵ By using this method, surgeons can achieve segmental fixation in thoracic segments that have severely narrowed pedicles.

Thoracic pedicle anatomy can be varied in patients without deformity, but patients with coronal deformity are noted to have significant variations in pedicular size, especially on the concave side of the curve. To this end, Watanabe et al.⁴⁶ performed an extensive evaluation of 1,021 thoracic pedicles instrumented during scoliosis surgery in 53 patients. They classified the pedicles based on the cancellous channel: type A—Large cancellous channel with pedicle probe passing easily; type B—Small cancellous channel with pedicle probe passing snugly; type C—Cortical channel requiring the surgeon to tap the pedicle probe with a mallet in order to advance; and type D—Slit/absent pedicle requiring a juxtapedicular screw position (Figs. 99.1 and 99.3; Watanabe, 2010). The authors also noted that 90% of the thoracic pedicles in the study population had a cancellous channel (type A or B) and 7% had cortical channels (type C). On the convexity, 98.2% of the pedicles had cancellous channels, whereas 81.5% of the pedicles on the concavity had cancellous channels.⁴⁶ This information is important when planning thoracic pedicle fixation in deformity surgery.

Accuracy

Over the past 20 years, multiple investigators have examined the accuracy of thoracic pedicle screw placement. The most useful data from the literature regarding accuracy come from studies with patients who have been treated with thoracic pedicle screws and had a CT scan postoperatively. When examining this accuracy data, one must carefully note the definition of an inaccurately placed thoracic

Figs. 99.3A to D: Classification of thoracic pedicle morphology according to Watanabe et al.⁴⁶ Parts (A) and (B) demonstrate thoracic pedicles with cancellous channels. Part (C) has a cortical path requiring a mallet in order to create a pedicle channel, whereas part (D) has a slit morphology that requires a juxtapedicular pedicle screw position.

Source: Adapted from Watanabe K, Lenke LG, Matsumoto M, et al. A novel pedicle channel classification describing osseous anatomy: how many thoracic scoliotic pedicles have cancellous channels? *Spine (Phila Pa 1976)*. 2010;35(20):1836-42.⁴⁶

pedicle screw. Some authors with strict criteria will define any cortical breach as a miss, whereas most will only define an inaccurately placed pedicle screw as outside the “safe zone.” The safe zone was originally described by Gertzbein and Robbins,⁴⁷ who defined a 4-mm zone around the pedicle that was composed of 2 mm each of epidural space and subarachnoid space. Some have questioned this notion because of cadaveric studies⁴⁸ and anecdotal observations that the spinal cord is directly adjacent to some pedicles, especially on the concave side in coronal deformity. Nevertheless, Belmont et al.⁴⁹ defined < 2 mm as a reasonable medial safe zone whereas lateral pedicle wall violation had a higher tolerance up to 6 mm because of the presence of the rib head to protect the lung pleura. In large series’ reporting thoracic pedicle screw accuracy, only two report a neurologic deficit as a result of an errant pedicle screw and both had > 4 mm medial encroachment.⁴⁷⁻⁵⁰

Modern era studies report thoracic pedicle screw accuracy rates of 1–12.7%.^{6,35,36,49-54} The majority of these studies consider pedicle breaches that are within the safe zone to be accurately placed. This is appropriate given the inherent safety of the screws placed within this zone. Belmont et al.⁴⁹ performed an extensive analysis of 279 thoracic pedicle screws in 40 patients who were evaluated

postoperatively with CT scan. Using a freehand technique, the authors reported a 99% accuracy rate with a defined safe zone < 2 mm medially and < 6 mm laterally. In a large study, Suk et al.⁶ examined 4,604 thoracic pedicle screws and reported an accuracy rate of 98.5%, although it should be noted that not all patients were evaluated with a post-operative CT scan. Another investigation of 577 thoracic pedicle screws defined a missed pedicle screw as one in which the central axis of the screw was out of the pedicle.³⁵ They demonstrated an accuracy rate of 93.8%. More recent studies have reported accuracy rates of 97%,⁵³ 98%,⁵⁴ and 94.9%.⁵⁰ These data demonstrate that, using modern techniques, thoracic pedicle screws can be accurately placed in patients who require segmental thoracic spinal fixation.

Biomechanics

Biomechanical studies have demonstrated factors that are important when using thoracic pedicle screws in order to maximize the stability of thoracic pedicle screw constructs. Kuklo et al.⁵⁵ tested the maximal insertional torque of thoracic pedicle screws by using a tap that was the same diameter, 0.5-mm smaller, or 1.0-mm smaller than the diameter of the pedicle screw. They demonstrated that undertapping the pedicle by 1.0 mm improved pedicle screw maximal insertional torque.⁵⁵ In another cadaveric study, Deviren

et al.⁵⁶ showed that more thoracic pedicle screws are required for stability if there is preoperative instability or instability created intraoperatively. In deformity patients, a thoracic pedicle screw placed using the “in-out-in” technique for dysplastic pedicles has been demonstrated to have 75% of the pullout strength of an intrapedicular screw.⁵⁷ Moreover, there is a drop in biomechanical strength when a breach occurs while trying to place a straightforward thoracic pedicle screw, and it is salvaged with an anatomically placed thoracic pedicle screw.³⁹ Additionally, Paxinos et al. demonstrated the importance of bone mineral density in thoracic pedicle instrumentation.⁵⁸ They showed that the pullout force of any posterior thoracic instrumentation in osteopenic bone was one-fourth the strength of the same instrumentation in normal bone.⁵⁸ In the setting of pedicle screw fixation in osteoporotic bone, pedicle augmentation with polymethylmethacrylate prior to screw placement has been found to increase biomechanical fixation⁵⁹ and potentially improve results.⁶⁰

CLINICAL UTILITY

Outcomes

The majority of the outcomes related to the use of thoracic pedicle screws are in deformity patients. Overall, thoracic pedicle screws allow for an improved correction of the coronal deformity, but patient outcomes using validated instruments have failed to show significant differences between pedicle screws and alternative instruments. An early study clearly documented the improved deformity correction using all pedicle screw constructs, but the authors did not report validated patient-reported outcomes.⁶¹ In a more recent study, Lehman et al.⁶² reported the intermediate-term outcome of adolescent idiopathic scoliosis and demonstrated the following corrections: 68% for the main thoracic, 50% for the proximal thoracic, and 66% for the thoracolumbar/lumbar curve at final follow-up. They also reported Scoliosis Research Society (SRS) scores of 83% at final follow-up. In another retrospective cohort study, Di Silvestre et al.¹² compared adolescent idiopathic scoliosis (AIS) patients treated with pedicle screw-only constructs versus hybrid constructs and demonstrated improved curve correction but no difference in the SRS-30 Health-Related Quality of Life or Short Form-30 outcomes. Others have mirrored these results.^{10,11,13,14,63}

Some of the most important data related to the use of thoracic pedicle screws is the avoidance of anterior

procedures in deformity patients. A classic study showed that anterior procedures negatively affect postoperative pulmonary function in deformity patients.¹⁸ Thoracic pedicle screws have allowed surgeons to avoid violation of the thoracic cavity because of the significant biomechanical advantage offered by three-column fixation. In a direct comparison of all-anterior versus all-posterior surgical approach for Lenke 5C scoliosis, Geck et al.¹⁶ demonstrated shorter hospital stays and better and stable curve correction at a minimum of 2 years. The avoidance of an anterior approach in the thorax may be one of the most compelling reasons to utilize thoracic pedicle screws.

There is a paucity of reported outcomes for the use of thoracic pedicle screws in trauma, degenerative conditions, infection, and tumor surgery. The authors of one retrospective thoracolumbar trauma series reported 12.7% pedicle screw breach (or failure) rate, with no complications related to the missed screws.³⁶ In this series, there were four complications, but only one related to rod breakage. Despite extensive use of thoracic pedicle screws in other surgical conditions requiring thoracic fixation, there is minimal data on outcomes related to their use.

Complications

When thoracic pedicle screws were first introduced, one of the main concerns was the risk of injury to surrounding neurologic and vascular structures. Given the close proximity of these structures,^{44,48} this concern is valid. Other structures, such as the lung and esophagus, are also at risk when placing thoracic pedicle screws. Li et al.⁶⁴ performed a retrospective review of complication rates in 208 deformity patients who were treated with 1,123 thoracic pedicle screws. They reported a complication rate of 16.5%, which they categorized as either directly or indirectly related to the pedicle screws (Table 99.1).⁶⁴ Other large retrospective series examining thoracic pedicle screws have reported complication rates. Suk et al.⁶ reported 67 screw malpositions (1.5%) in 48 patients (10.4%) and Kim et al.³⁵ reported 36 screw malpositions (6.2%; Table 99.1).

The results from these large retrospective cohort studies demonstrate that the most common complications related to thoracic pedicle screws in deformity patients are aberrant screw placement and cerebrospinal fluid leaks. Despite the screw malpositions that were reported, these studies demonstrated only two transient neurologic complications, with no vascular or visceral complications (Table 99.1). The infection rates in these studies are not

Figs. 99.4A and B: Computed tomography (CT) scan demonstrating a malpositioned thoracic pedicle screw with the tip of the screw abutting the descending thoracic aorta (A). After removal of the screw secondary to patient complaints of an ipsilateral thoracic radiculopathy related to the pedicle screw, CT angiography displays subtle dye leakage and pseudoaneurysm of the aorta (B). The patient developed abdominal pain postoperatively that was attributed to mesenteric ischemia secondary to thromboembolic disease. The patient's abdominal pain was completely relieved after 48 hours of anticoagulation with heparin.

directly related to thoracic pedicle screw instrumentation, as similar rates are likely to have occurred using alternative thoracic fixation techniques. Vascular complications have been reported in other small series and case reports⁶⁵ as well as anecdotally (Figs. 99.4A and B: CT angiography

of a recent Cheng patient with a screw in the aorta). Despite these reports, multiple large series in the literature demonstrate a very low incidence of complications related to the use of thoracic pedicle screws.

Complications seen with longer follow-up are also important. A short retrospective series detailed proximal junctional vertebral fracture or subluxation in 10 patients who underwent adult deformity surgery³⁰. These can be catastrophic failures because two patients with fracture of the proximal level and vertebral subluxation one level above had Frankel B neurologic injuries as a result of the injury. The authors noted that old age, osteopenia, preoperative comorbidities, and severe preoperative global sagittal imbalance were risk factors for this complication.³⁰ It is possible that the superior biomechanical fixation provided by thoracic pedicle screws allowed for greater correction of the deformities but predisposed these patients to proximal junctional failure.

There is a risk profile associated with the use of thoracic pedicle screws. Despite the risk profile, these techniques can be employed safely and the risks can be minimized with careful indications, decision-making, and surgical techniques.

CONCLUSION

Thoracic pedicle screws are important in modern spine surgery. They allow for three-column fixation of the thoracic

(NR: Not reported).

spine, thereby allowing for greater correction in deformity surgery and greater stability in trauma, degenerative, tumor, and infection. There are several advantages and disadvantages to using thoracic pedicle screws that are relevant in the surgical treatment of a thoracic spine condition. If surgeons are thoughtful in their use of thoracic pedicle screws, the advantages can outweigh the disadvantages. Surgeons are increasingly more competent with the use of thoracic pedicle screws, given the frequency with which they are used. Several techniques exist for placing thoracic pedicle screws. Each surgeon should use the technique that is the most effective and efficient in his or her own hands. In this way, patients can have improved outcomes after thoracic pedicle screw instrumentation while minimizing the risk of complications.

KEY POINTS

- Thoracic pedicle screws provide greater correction and stability than other types of fixation through three-column fixation.
- Thoracic pedicle screws have concomitant drawbacks including risk of proximal junctional kyphosis, potential neurologic and vascular complications, and increased cost.
- A thorough understanding of thoracic spine anatomy and pedicle morphometry is necessary for safe placement of screws in this region.

INTRODUCTION

During the last few decades, the development of powerful implants, the introduction of the microscope/endo-scope, and intraoperative real-time three-dimensional imaging have positioned spine surgery at the cutting edge of technology. Since the early 1990s, different surgical approaches have been published using “less invasive access techniques,” based on the premise of minimizing damage to functional tissue in order to avoid associated morbidity without compromising the goals of the surgery.¹ This process has compelled the practitioners of minimally invasive spine surgery (MISS) to prove that less invasive procedures are at least as safe and effective as “gold standard” open procedures.

SURGICAL APPROACHES

Among the anterior thoracic approaches, both the transpleural and the retropleural^{2,3} techniques are commonly used. Anterior exposures have the following advantages over their posterior-based counterparts:

- Directly addresses the affected lateral side
- Keeps most structures important for spinal stability intact
- Higher fusion rate due to relatively large endplate surface area
- Better visualization of the spinal canal with negligible dural sac manipulation.

POSITIONING

The patient is positioned straight laterally, ensuring that the spine lies parallel to the table and securely fixed. Using the C-arm, the surgeon carefully identifies the surgical level. The surgical level should be identified prior to the approach and, again, before any work on the spine begins.

A given approach can be performed from either side. When approaching from the patient’s right side, one must keep in mind that the dome of the diaphragm may obscure the view of the lower thoracic levels and must be held out of the operative field. However, the right side offers a wider working area, especially in the upper and middle thoracic regions, because the aorta and the thoracic duct are located on the left. Therefore, the left-sided approach is often preferred at lower thoracic levels as the diaphragm is more easily kept out of the surgical field and the lateral decubitus position allows the kidney and spleen to move anteriorly (Fig. 100.1). The aorta and thoracic duct lie anteriorly in the midline, leaving the lateral aspect of the spine freely accessible.

APPROACH

Preoperative skin marking varies somewhat according to the shape of the thorax and rib angulation. The incision is typically made two intercostal spaces superior to the

Fig. 100.1: Lateral decubitus patient positioning.

Fig. 100.2: The rib is sectioned after subperiosteal dissection.

Fig. 100.3: The pleura is intact and the rib stump is detached from the thoracic wall.

Fig. 100.4: Retractors in place.

targeted vertebral body or disc space.⁴ The muscle layers are divided parallel to the skin incision until the underlying rib is exposed over a length of 8–10 cm. From this step onward, the transpleural technique splits the pleura parallel to the ribs. After the lung is collapsed, a rib spreader is used to enlarge the intercostal space and open the chest cavity to expose the spine.

The retropleural approach is technically more demanding. After uncovering the rib, the periosteum is dissected and elevated followed by detaching the pleura and endopleural fascia from the deep costal surface, taking care not to violate the pleura (Fig. 100.2). The neurovascular bundle is isolated from the undersurface of the lower border of the rib. A single- or double-“window” osteotomy

of the rib is performed. Resection of two ribs may be performed for a wider field of view or when the surgeon plans to use the rib for structural autograft.

After displacing the rib cranially or caudally or removing it completely, the endopleural fascia is divided and the parietal pleura is elevated from the thoracic wall, thus entering the retropleural space. Further dissection down to the head of the rib and vertebral body is performed using finger or instrument dissection, taking care to avoid direct pressure against the fragile pleura, which can be easily disrupted (Fig. 100.3). Once the exposure is complete, a self-retaining retractor is placed. The detached pleura and the deflated lung are gently retracted anteriorly allowing visualization of the spinal column and the affected segment (Fig. 100.4).

As the surgical field is relatively small, some source of illumination and magnification is required in order to visualize the anatomy properly. In addition to a light source, a surgical microscope or endoscope can be used.⁵

■ ENTERING THE SPINAL CANAL

Using a combination of clues from preoperative imaging, anatomical landmarks, and intraoperative imaging, the surgeon can now begin with the planned decompression. Anatomically, the anterior border of the spinal canal is made up of the posterior wall of the vertebral body, the posterior annulus fibrosus, and the posterior longitudinal ligament. The lateral boundary is defined by the intervertebral foramen, which is covered by the costal head between the second and tenth thoracic vertebrae.⁶ Uncovering the foramen is the quickest, simplest, and safest way to gain access to the spinal canal. Exceptions to this include conditions such as discitis or tumors that can cause destruction of the normal canal boundaries.

Rib head removal can be performed with a burr, an oscillating saw, or an ultrasound device such as a bone scalpel. Once the foramen is free, the portion of the pedicle caudal or cranial to the disc can be removed to further uncover the dura.^{7,8} Care must be taken to minimize venous bleeding from elevated pressure in the compressed epidural venous plexus; such bleeds can often be stopped with gentle pressure using a fibrin sponge or other hemostatic agents. If a complete vertebrectomy is not planned, there is no need to ligate the segmental arteries as they rarely interfere. When resecting a large intracanal mass-occupying lesion, it may be necessary to perform a partial vertebrectomy of the posterior aspect of the neighboring vertebrae extending as far cranially, caudally, or medially as necessary.⁹ In the case of a vertebral body resection, the vertebrectomy can be performed once the segmental arteries have been ligated. By doing so, the exposure is enlarged, gaining wider access to the ventral portion of the canal and helping to ensure that the surgeon will not place unnecessary pressure on the already compromised spinal cord.

■ WORKING INSIDE THE CANAL

Once a partial corpectomy defect has been created, the surgeon can focus on dissecting and resecting any pathologic process by drawing it into the ventral defect. When removing bone or a calcified disc, care should be taken to remove fragments under careful control as sudden release

and a snapping back of tethered fragments will percuss the cord, resulting in a spinal cord contusion and bleeding that may lead to a neurologic deficit. The posterior longitudinal ligament is divided as necessary for further access to the thecal sac. In long-standing pathology or calcified processes, the ligament can be very adherent to the dura, making detachment tedious and possibly leading to a dural tear. Epidural bleeding is often an indirect sign that cord compression still exists. Bleeds can be controlled using either bipolar forceps or small pieces of gel foam placed between the dura and the anterior margin of the canal. Dural pulsation and lack of epidural bleeding are signs that complete decompression has been achieved.

■ RECONSTRUCTION, INSTRUMENTATION, AND CLOSURE

Following a discectomy with minimal bony resection, reconstruction may only require the placement of a structural bone graft. In most cases, this will not require the addition of instrumentation; the vertebrae and spinal canal will remodel and achieve stability simply with a bone graft reconstituting the surgical defect.¹⁰ When an extensive resection or vertebrectomy has been performed, the anterior spinal column must be reconstructed in order to maintain its load-bearing capacity. The technique used for this procedure has been previously described.¹¹⁻¹³ Briefly, a thorough decompression is performed using burrs, curettes, osteotomes, and pituitaries. Next, an interbody spacer consisting of a metallic or polymer cage—fixed or expandable—or an allograft or autograph bone strut is selected. For reconstruction after infection, an autologous structural iliac crest strut is often preferred. An expandable cage may be used and introduced into the cavity and progressively distracted until adequate distraction of the interspace is accomplished. Fixed cages or structural bone grafts must be carefully selected or reshaped to fit the space that exists for an optimum press fit. Anterior instrumentation with plates and screws may be added to reinforce the spine's load-bearing capacity and to protect the implant from subsidence or expulsion until fusion has been achieved, especially if no posterior instrumentation is used.

Closure of the operative site may then be initiated. After placing a drain, the lung is ventilated and re-expanded, pushing the parietal pleura back to its natural position. The soft tissue is then closed in layers (Fig. 100.3). If not used for reconstruction, the resected rib may be replaced and fixed using either absorbable stitches or titanium mini-plates.

DISCUSSION

Is the Term “Direct Lateral Approach” Appropriate for the Thoracic Spine?

During the last couple of decades, the extreme lateral or direct lateral approach was popularized for the treatment of lumbar spine disorders.¹⁴ These techniques either split or retract the psoas muscle fibers while avoiding injury to the lumbar plexus in order to reach the spine.¹⁵ By revamping older approaches¹⁶ and using modern instruments (i.e. expandable tubular retractors), surgeons have adapted this technique for the thoracic region, keeping the term “direct lateral” (Fig. 100.4). When approaching the thoracic spine, there is no muscle overlying the lateral aspect of the spine above the proximal extent of the psoas muscle, which originates from the transverse process of T12. In a strict sense, all approaches to the thoracic vertebral bodies must be considered a “direct lateral” technique. These include the transthoracic transpleural (including mini-thoracotomy), thoracoscopic, and retropleural approaches (Fig. 100.5).

Rationale for an Anterior Approach

The aim of any type of surgery is to achieve optimal results while minimizing what has been termed “approach-related trauma.”¹⁷ Spinal stability is based on three pillars: integrity of the spine and supporting structures, neurologic status, and pain level. In modern spine surgery, attention to preserving quality and function of the injured tissue plays a major role. Direct approaches to the anterior thoracic spine aim to reduce soft tissue trauma and risk of injury to the neural elements.

Surgical decompression and reconstruction techniques of the thoracic and thoracolumbar spine have undergone a dramatic evolution during the last few decades. Forty-four years ago, Perot described a thoracotomy for the treatment of degenerative disease of the spine.¹⁸ The unobstructed view of the thecal sac provided by this technique remains the most reliable method for achieving decompression in the patient with a neurologic deficit due to a space-occupying lesion within the spinal canal. During the last 20 years, various anterior procedures have gained widespread acceptance in cases where anterior column reconstruction, or correction of collapsed or kyphotic segments, is needed to restore the load-bearing function of the spine.¹² The anterior approach has also been

Fig. 100.5: Angle of approach.

particularly useful in the treatment of fixed thoracolumbar scoliosis.¹⁹ Anterior release increases the flexibility of the spine in patients with rigid curves and facilitates segmental correction. This can be accomplished using either intervertebral grafts or posterior reduction maneuvers for staged procedures to improve sagittal and coronal correction while minimizing the number of fused levels.²⁰

Compared with the transpleural approach to the thoracic spine, the notable differences with the retropleural approach are the wound size as well as the extent of damage to the diaphragm. Complications such as paralysis of the diaphragm and atelectasis can occur after iatrogenic diaphragmatic injury.²¹ The pleura often acts as a natural barrier between a neoplasm or infectious focus and the pleural cavity.^{22,23} Surgery performed with less invasive techniques may mitigate such complications by limiting collateral damage to the surrounding soft tissues. Rosenthal et al. demonstrated a significantly lower level of infection in MISS cases compared to open.²⁴ There is, however, limited evidence to suggest that results using smaller incisions or less aggressive exposures are superior to the open approach. Nevertheless, it stands to reason that unnecessary approach-related tissue injury should be minimized whenever possible, provided surgical outcomes are equivalent.

Advantages of Direct Lateral Approach

- Approaches from the side of pathology
- Wider surface to achieve fusion compared to posterior procedures
- Decreased amount of time with prolonged lung deflation with MISS techniques compared to traditional thoracotomy²⁵
- Decreased need for a thoracic surgeon due to lower risk of injury to vasculature
- Three options to perform the approach (retropleural, mini-open, and thoracoscopic)
- Continuous visualization of anterior structures and of the spinal cord
- Potential for less perioperative morbidity and trauma to patient compared to traditional thoracotomy²⁴

Disadvantages

- Not suited for the upper thoracic level (above T3) due to the shoulder-clavicular complex
- Steep technical learning curve

Although posterior approaches have also been tailored to the use of retractors and percutaneous systems, muscle and bony surgical injury are often more extensive than with anterior techniques.

CONCLUSION

In 1987, Wickham published the first paper defining the term “minimally invasive” as “minimal damage of biologic tissue at the point of entrance of surgical instruments.”²⁶ Almost 20 years later, Seldomridge attempted to explain the term “minimally invasive spine surgery”: “The primary goal of minimally invasive spinal surgery is to minimize paraspinal muscle retraction and dissection in the hope that this will lead to reduced blood loss and postoperative pain, acceleration of the recovery period, and improve clinical outcomes.”²⁷ The primary goal of less invasive surgery is the reduction in tissue damage and functional damage to the motion segment in order to minimize postoperative pain, use of analgesics, and blood loss. These goals must always remain secondary to achieving comparable or superior results versus traditional techniques.

It is in human nature to continuously examine all aspects of treatment scientifically, to attempt to push the envelope further, and to improve results and reduce

patient's risk. Keep in mind Ford's quote as it pertains to spine surgery, implying that innovation is not necessarily better or worse, but rather a different way to solve a given problem.

KEY POINTS

- The patient is placed in the lateral decubitus position on the same side as the disc herniation or space-occupying lesion. The skin incision is made two disc levels above the pathology, and entry is gained into the thorax just above the superior edge of the rib
- To gain access to the spinal canal, costal head resection followed by pediculectomy of the cranial and/or caudal segments results in better visualization of the dura
- With MISS, there is reduced ability to address many spinal levels compared to an open thoracotomy, but the reduced soft tissue damage may be of benefit in patients with significant medical comorbidities²⁸
- The direct lateral approach avoids the extensive muscle dissection associated with posterior approaches and provides a direct view of anterior or lateral pathology²⁴
- The direct lateral approach provides the same exposure as traditional thoracotomy exposures, but does not require single lung ventilation, a large incision, or extensive rib resection²⁹

- » Bone Tumors
- » Psychosomatic Pain

INTRODUCTION

Back pain in the pediatric age is an uncommon clinical complaint and is significantly rare than in adults. In the absence of traumatic insult, back pain in children and adolescents frequently denotes serious underlying pathology. The one-year prevalence rate of low back pain in children has been reported from 7% to 58%.¹ Pain beyond duration of 3 weeks warrants careful and thorough investigation performed by clinical, laboratory, and imaging examinations. Describing difficulty, special stress world in childhood, and other psychosocial history should also be assessed.

DEFINITION OF BACK PAIN IN CHILDREN

Nonspecific back pain has been found as the most common type of back pain in children.² Visual analog scale seems to be still the most practical scale for measurement and follow-up of the intensity of pain in children. For limited reliability history from children or their parents, more validity and reliability scales for assessment of pain intensity in children are mandatory. Recently, some new standard scales for assessment of pain intensity in children with acceptable validity and reliability have been developed.^{3,4} FACES Pain Rating Scale³ that works on the basis

of the facial expressions and has been quantified in recent studies can also be used by the pediatricians to measure the intensity of the pain in children. For children of <7 years and >2 months, FLACC (Facial expression, Leg movement, Activity, Cry, Consolability) has been validated.⁴ After pain severity assessment, diagnosis of different categories should consist of an algorithmic clinical approach. Bunnell suggested mechanical, developmental, inflammatory, and neoplastic processes for lower back pain in pediatric patients.⁵ Rodriguez and Poussaint categorized the possible diagnosis in children (Table 101.1).⁶

HISTORY

Taking complete and accurate history is most important for the pathological diagnosis in the pain of children. In fact, difficulty answering basic clinical question and secondary history from parents may be the most obstacles in history recording.

The physician should ask the patients regarding the onset of symptoms, description of the pain characteristics including location, duration, presence or lack of radiation, and also exacerbating and alleviating factors. To differentiate between mechanical and inflammatory types of pain, the physician should ask the patients whether they have morning stiffness or reduction of pain after activity.

Table 101.1: Etiologies of low back pain in children and adolescents.

- I. More common musculoskeletal and mechanical etiologies
 - A. Nonspecific low back pain
 - Muscular strain
 - B. Special diagnosis
 - Spondylolysis/spondylolisthesis
 - Malalignment
 - Scheuermann disease
 - Scoliosis
 - Intervertebral disc herniation
- II. Other etiologies
 - A. Vertebral column fractures
 - B. Infectious diseases
 - C. Inflammatory
 - Ankylosing spondylitis
 - Juvenile idiopathic arthritis
 - Arthritis
 - D. Neoplastic disorders
 - Spinal column
 - Primary neoplasms
 - Secondary neoplasms
 - Spinal cord
 - Intramedullary
 - Extradural tumors
 - Intradural-extradural
 - E. Congenital and hematologic diseases

Inflammatory type of pain normally increases after prolonged rest and reduces by physical activity. Therefore, increase of pain intensity after walking for a long period of time implies more on mechanical pain. When taking history, the physicians should also think on some familial conditions and ask for family history of neurological and rheumatological diseases as well as congenital abnormalities. It should be emphasized that back pain may be a neurological symptom of the neurological system involved. Other neurological function-related message should be collected, such as walking distance, daily activity, extremity atrophy, numbness, muscle weakness, and so on.

PHYSICAL EXAMINATION

It is preferable to perform a complete physical examination in all the children with lower back pain (LBP). General surveys include general behavior, mannerisms, patients' details location, and severity of their symptoms. Sagittal alignment should be viewed from sided observation. Any skin anomalous should be recorded including hairy patches, pigmentation, dermal sinuses, and so on. Palpation should not only be focused on the reported pain

location, but also on whole spine. Pelvic examination should be performed, such as Thomas' test, Trendelenburg test, Patrick's test Flexion, ABduction, and External Rotation lower limbs for hip joint test (FABER), and Ober's test. Then a complete neurological examination should be performed in all children with LBP, necessarily strength and sensation in lower extremities and deep tendon reflex, to reveal any possible underlying intraspinal pathologies in these patients. The core stability of the children, as in the case of any weaknesses, and lack of coordination in paraspinal and lateral abdominal muscles should also be assessed. Some major clinical examinations that should be performed in the children with LBP are Adams's forward bending test, straight leg raise (SLR), or Lasegue test. Other joints are assessed for flexibility and range of motion. Secondary sexual characteristics should also be recorded for any developmental assessment and related endocrine system pathology.

LABORATORY EVALUATION

When suspicious, a systemic, inflammatory, or infectious process, complete blood count, erythrocyte sedimentation rate (ESR), serum C-reactive protein (CRP), rheumatoid factor, HLA-B27 test should be performed. While clinical circumstances indicate infection, blood and urine cultures are mandatory. Further chemical panel may be needed for causes of back pain.

RADIOGRAPHIC EVALUATION

Plain Radiograph

The plain radiographic evaluation of the spine is the basic and first radiographic examination for assessing lower back pain. Commonly, anteroposterior (AP) and lateral views are selected for screening. In the AP view, coronal alignment, symmetry and rotation of pedicle, width of pedicle, interpedicular and interspinous distance, and other bony structure of vertebral should be evaluated. Lateral view can accommodate message of alignment of sagittal spine, intervertebral disk, and integrity of endplate. Nonrotational scoliosis often indicates the pathological segment. If obvious scoliosis or kyphosis deformity is found in the lumbar spine X-ray or chest film, a full spine radiographic evaluation is indicated for a general alignment evaluation. Also coronal bending and lateral flexion and extension radiographs should be included for evaluating the flexibility of spinal deformity while the therapeutic

choice is required. Oblique X-ray is specially indicated for the suspicious pars pathology.

Radionuclide Bone Scanning and Single Photon Emission Computed Tomography Scanning

For more than 30 years, radionuclide bone scanning has been known as one of the most sensitive noninvasive methods to detect focal bone pathology. A key advantage is high sensitivity, higher than computed tomography (CT) or standard radiography. In the majority of nuclear medicine institutions, bone scans are currently obtained in whole-body technique using double-head γ camera systems equipped with high- or even ultrahigh-resolution collimators. Single-photon emission computed tomography (SPECT) is performed for focal abnormalities. This technique enables the accurate localization of tracer accumulations, especially in anatomical regions that are otherwise difficult to interpret because of complex architecture of skeletal structures such as the spine, pelvis, or skull.

The radiopharmaceutical most often used in bone scintigraphy is ^{99m}Tc -methylene diphosphonate. This compound binds to bone by chemisorption to the hydroxyapatite crystal. Two to six hours after intravenous injection, ~50% of the injected dose is accumulated in the skeletal system. Enhanced uptake (focally or diffusely) reflects increased bone turnover caused by changes of bone vascularization and/or osteoblastic activity.

Bone scanning with ^{99m}Tc -methylene diphosphonate detects abnormalities of bone metabolism as early as 24–48 hours after the onset of pathology. Thus, fractures and other manifestations of bone stress can be diagnosed very sensitively by bone scintigraphy.

On the other hand, bone scintigraphy can be used successfully in ruling out bone infection. If triple-phase bone scintigraphy is negative and vascular problems can be excluded, osteomyelitis is most unlikely. Nonetheless, leukocyte scanning using ^{111}In - or ^{99m}Tc -labeled leukocytes or granulocytes is still the gold standard to diagnose bone infection. It is known to be highly sensitive as well as specific.⁷ Recently, new multimodality imaging technique combining high-resolution structural images (CT) and functional radionuclide scan images (SPECT) has been developed. It is chiefly reserved for patients in whom the whole-body scan shows one or more images of unclear significance. This hybrid imaging

modality combines structural and functional images, which has considerably improved the imaging of patients with malignancies.⁸

Computed Tomography

Since CT introduced into clinical scenario, it has brought a large amount of diagnostic clues of bony pathology. Later evolution of computer techniques, three-dimensional (3D), super thin-sliced CT can figure out more specific trauma or pathological lesion. Computed tomography is also a helpful diagnostic tool for lumbar disc herniation and canal stenosis. Although magnetic resonance (MR) has brought more direct sensitivity for soft tissue pathology, CT is still superior to MR and plain X-ray for its high-quality bony lesion and 3D reconstructive views. For low back pain in childhood and adolescent, CT can demonstrate more diagnostic message in spondylolysis,⁹ bone lesion, congenital anomalous, and other bony pathology.

Magnetic Resonance Imaging

Magnetic resonance techniques have revolutionized the evaluation of low back pain in children and adolescents. The noninvasive and high sensitivity has made MR the first choice of most spine pathology. Magnetic resonance is very useful in demonstrating neurological structures and soft tissue around the cord. Common MR scan sequence includes T1, T2, spin echo, and fat echo, which provide ability to show contrast of different tissues. Another most used MR technique is T1 sequence with contrast agents, which help identify spinal tumor, separation of scar, and recurrent disc herniation.

According to different clinical entities, MR has different advantages. For disc degeneration diseases, not only it facilitates the assessment of neurological compressive condition, but also it can demonstrate the degree of degenerative process. Pfirrmann has divided the disc into five grades according to its structure, distinction of nucleus and annulus, signal intensity, and disc height,¹⁰ as listed in Table 101.2. Annulus tear can present high-intensity zone in MR T2 sequence, which is reported to be related to lower back pain and positive discography. Degenerative endplate can show modic changes, which are correlated with the prevalence of back pain, therapeutic strategy, and prognostic values.^{11–13} For spondylolysis, MR may bring messages of acute or chronic process of pars defect, which also has prognostic values of treatment. For spine infection, MR may indicate the severity of discitis,

Table 101.2: Classification of disc degeneration*.

<i>Grade</i>	<i>Structure</i>	<i>Distinction of nucleus and annulus</i>	<i>Signal intensity</i>	<i>Height of intervertebral disc</i>
I	Homogeneous, bright white	Clear	Hyperintense, isointense to cerebrospinal fluid	Normal
II	Inhomogeneous with or without horizontal bands	Clear	Hyperintense, isointense to cerebrospinal fluid	Normal
III	Inhomogeneous, gray	Unclear	Intermediate	Normal to slightly decreased
IV	Inhomogeneous, gray to black	Lost	Intermediate to hypointense	Normal to moderately decreased
V	Inhomogeneous, black	Lost	Hypointense	Collapsed disc space

volume of abscess, and direction of abscess interfering, and also differentiate infection and tumor.¹⁴ Superiority of MR for assessment of neurological structure has made it the first choice to identify congenital neural tube developmental dysfunction. Many investigators recommend MR as the mandatory preoperative examination of congenital spine deformity, which has 20–30% rates of intracanal anomalous conditions.

SPECIAL CLINICAL ENTITIES

Lumbar Disc Herniation

Lumbar disc herniation is not a common cause of lower back pain among children and adolescents. The onset of symptoms in a child is less acute and severe, while in an adolescent it is present with an acute process. The real incidence of pediatric disc herniation in lumbar disc excisions of all ages seems difficult to establish and is reported

to range from 0.4% to 3.8%.^{15–17} Prevalence in adolescent athletes has been reported to increase.¹⁸ One of the most likely factors accounting for the early onset of lumbar disc herniation is its association with vertebral deformities, such as scoliosis, transitional defects, schisis, and canal narrowing. In these cases, the reported incidence ranges from 30% to 70%,^{19,20} compared with 15% cases in a healthy population.²¹ These alterations can cause an anomalous biomechanical stress for disk. Additionally, many authors hypothesize familial predisposition to be another etiologic factor for disc herniation and some evidence was found.²²

The diagnosis of lumbar disc herniation still depends on the physical examination and image tools. The SLR test and other nerve root localization signs are the best evidence for identified diagnosis of lumbar disc herniation. Then, definitive diagnoses require MR or CT confirmation (Fig. 101.1).

Conservative treatments of disc herniation cover bed rest, activity restriction, and anti-inflammatory medications. Some authors reported that bracing has an accepted results.²³ Other investigators suggested high failure rate of conservative treatment. Surgery is recommended for failure of conservative treatment, and decompressive laminectomy and discectomy are the standard procedures. Mayer reported the results of using percutaneous endoscopic discectomy for pediatric and juvenile lumbar disc herniations. During the 1–5-year follow-up, all four cases acquired good-to-excellent outcomes without any complications.²⁴

Spondylolysis and Spondylolisthesis

Spondylolysis and spondylolisthesis have been widely accepted as the most underlying causes of low back pain among children and adolescents.²⁵ Spondylolysis is a defect in the neural arch, most commonly the pars interarticularis. Spondylolisthesis is an anterior translation of one vertebra on another or on the sacrum. The reported incidence is 6% in general population, but varied in different ethnic groups or in people who engage in different sports. Spondylolysis and spondylolisthesis have been referred to as congenital anomalies of the spine, but there is no supporting embryological or anatomical evidence for this assumption.

Spondylolysis occurs in children rarely before 5 years, more commonly in 7–8 years, and increase until 20 years.^{26,27} Most authors believed that stress and micro-trauma are important factors in the etiology. Athletic participation has been reported an increased incidence of spondylolysis and spondylolisthesis. Jackson noted that the incidence of spondylolysis in female athletes was 11% (four times higher than normal).²⁸ In adolescent athletes, spondylolysis is the cause of pain in an estimated 47% cases, compared to only 5% of pain in adult athletes. Football linemen and gymnasts have a higher likelihood of spondylolysis.²⁹ Therefore, a high-level sport-related low back pain should be suspicious of spondylolysis and spondylolisthesis.

The comprehensive classification of spondylolysis and spondylolisthesis was proposed by Wiltse.³⁰ This discussion is limited to isthmic (type II) spondylolysis and spondylolisthesis, the two types that commonly occur in children and adolescents. Some anatomical studies have suggested that shear stresses are more on the pars interarticularis when the lumbar spine is extended.³¹ In young people, the pars interarticularis is thin and neural arch

has not reached its maximum strength.³² A fatigue fracture of the pars interarticularis can occur at physiological loads during cyclic flexion–extension motion of the lumbar spine. The pain associated with an acute pars stress fracture is believed to be related to the biology of fracture site. Nordström noted that the pain of spondylolysis and spondylolisthesis might derive from the spondylolytic defect itself, probably from stretching of the local neural elements rather than from their sensitization/stimulation by local inflammatory mediators.³³ Low back pain, postural deformity, or abnormal gait resulting from tightness of the hamstrings would be the most common complaints of spondylolysis and spondylolisthesis. Symptoms are usually initiated or aggravated by strenuous activity, particularly the repetitive flexion extension of the spine. Physical examination may find tenderness in the lumbosacral region or restriction in truncal motion. Tight hamstrings may be found in patients with spondylolysis or any grade of spondylolisthesis, and this is seldom accompanied by neurological signs.³⁴ The tightness may be so extreme that the child cannot bend forward at the hips or during the straight leg-raising test. In lower-grade slip, tight hamstrings may be the only positive findings of physical examinations. Conversely, it would be common in high-grade slips, combined with mild scoliosis, flattening of buttocks, rotated pelvic, and compensated knee flexion for stand (Figs. 101.2A and B).

Lateral X-ray films are enough to demonstrate the grade of spondylolisthesis. If pars defect is large enough, it can be viewed in all radiographic examinations. Especially, if it is unilateral, as in 20–25% of patients, or if it is not accompanied by spondylolisthesis, it can be a very subtle finding that can be identified only by special radiographic techniques, such as oblique view, or flexion or extension lateral films.³⁵ Oblique radiographs of the lumbar spine are often necessary to view this area in relief, typically, a break in the pars interarticularis called “Scottie dog” sign. Libson noted that the diagnosis will be missed in 20% of young symptomatic patients if oblique radiographs are not made.³⁶ In fact, pars lytic lesion within the neural arch is not always present on plain radiographs. In the event of negative plain radiographs in a patient with back pain, bone scan with SPECT is a useful adjunct, especially for the prespondylolytic stress lesion.^{37,38} This will show an increased uptake at areas of the bone with increased turnover, so it will be positive with a stress reaction to stress fracture to complete fracture. If the SPECT is positive, CT

Figs. 101.2A and B: (A) Posteroanterior and (B) lateral standing radiographs of a 13-year-old girl with L5 symptomatic high-grade spondylolisthesis.

of the affected area is indicated for the morphology of the pars and the rest of the neural arch. A standard CT can also help with prognostication. If a pars defect is sclerotic, then it is most certainly a chronic defect and is less likely to heal with bridging bone. Udeshi and Reeves showed that using 3 mm on T1-weighted images and 4 mm on T2-weighted images they are able to adequately assess 98.2% of pars on T1-weighted images and 93% on T2-weighted images.³⁹

The treatment choice for spondylolysis and spondylolisthesis is based on the acuteness of pars defect and degree of spondylolisthesis, including observation, bed rest, restrict activity, exercise, bracing, and or surgery. Bracing is a wide-accepted therapeutic option. The acute injuries are treated with 12 weeks of bracing and the chronic injuries are treated until they are pain free. Although spondylolysis of long duration is not likely to heal, a clinical response to simple nonoperative measures can still be expected.⁴⁰ Micheli achieved 90% good-to-excellent results with antilordotic bracing in acute lesion.⁴¹ Iwamoto showed that in chronic lesion 88% of patients were able to return to their sport with rest and antilordotic bracing, at an average time of 5.4 months.⁴² Concerning to grade of spondylolisthesis, high-grade slips are always associated with intractable back or leg pain, progressive neurological symptoms, then surgery is generally recommended.⁴³ Direct repair should preserve the motion segment, but this is still a theoretical benefit without good evidence of patient's improvement when compared to fusion. Spine fusion is the most common choice for high-grade spondylolisthesis. Surgery strategy

Table 101.3: Risk factors of slip progress in low-grade spondylolisthesis.

<i>Clinical</i>	<i>Radiographic</i>
Adolescent growth	Dysplastic slip
Female	Domed sacrum
History of back pain	Slip > 40–50%
Increased motion in dynamic X-ray	

may cover fusion with or without reduction, decompression or not, fixation or not. A new grade proposed by Spinal Deformity Study Group, based on slip grade and spinopelvic alignment, is recommended in the evaluation and treatment of spondylolisthesis.⁴⁴ Severe index reported by Lamartina is helpful in identifying low-dysplastic developmental spondylolisthesis from high-dysplastic developmental spondylolisthesis (HDDS) and allowing earlier surgical stabilization to prevent slip progression.⁴⁵

The natural history of low-grade spondylolisthesis is considered benign, but the risk factor of slip progress should be assessed. Related risk factors are listed in Table 101.3.

Scheuermann's Kyphosis

In 1920, Scheuermann⁴⁶ first published a paper on thoracic or thoracolumbar spine kyphosis in adolescents. The pathological process of Scheuermann's kyphosis is characterized by vertebral wedging, endplate irregularity, and narrowing of the disc space with or without disc herniation (Fig. 101.3). The common main complaint of this condition

Fig. 101.3: X-ray of a 17-year-old boy showed kyphosis of thoracolumbar segment caused by multilevel vertebral wedging.

is not lower back pain but deformity or poor posture of parent's concern. Back pain is present in 20–30% of the cases. Its incidence ranges from 1% to 8% of the general population, although its true incidence is probably understated for attributed to poor posture.^{47,48} The main differentiated points of postural kyphosis from Scheuermann's kyphosis include the presence of a uniformly rounded kyphosis that is nonstructural, the absence of wedged vertebral bodies (VBs), and disc degeneration. Radiographically, the Scheuermann's kyphosis is the structural kyphosis accentuated on flexion films and does not resolve on extension films.

The etiology of Scheuermann's disease remains unknown. An increased familial incidence of Scheuermann's kyphosis is noted by several investigators.^{49,50} Damborg et al.⁵⁰ reviewed 35,000 twins to establish a cohort of symptomatic twins with Scheuermann's kyphosis recorded in the Danish twin registry. They found that the pairwise concordance for monozygotic twins was 0.19 compared with 0.07 for dizygotic twins. The probandwise concordance was 0.31 for monozygotic twins and 0.07 for dizygotic twins. Heritability was 74%. These findings indicate a major genetic contribution to the etiology of Scheuermann's kyphosis.

Histopathologically, Scheuermann indicated avascular necrosis of ring apophysis caused the wedging of VB although other investigated noted ring apophysis does not contribute to vertebral growth. Recently, Scoles noted disorganized enchondral ossification similar to Blount's disease, a reduction in collagen, and an increase in

mucopolysaccharides in the endplate, is noted in patients with Scheuermann's kyphosis.⁵¹ Mechanical factor is also considered for the fact that kyphosis may appear before VB wedging. Other investigators reported thickening of the anterior longitudinal ligament and partial reversal of the vertebral wedging after brace treatment, implying the mechanical theories of pathogenesis.^{52,53} Paaajaen showed degeneration of the disks on magnetic resonance imaging (MRI) in half of the young patients with Scheuermann's kyphosis as opposed to 10% of asymptomatic controls.⁵⁴ It is probable that multifactors contribute to the pathogenesis of Scheuermann's kyphosis, some genetic and some environmental; further investigation will be needed before any definite conclusions can be reached.

The onset of Scheuermann's diseases usually appears just before puberty, after ossification of the ring apophysis, as a structural kyphotic deformity of the thoracic or thoracolumbar spine. Two different curve patterns have been described in Scheuermann's kyphosis. The thoracic pattern is the most common and usually involves more than one level associated with a nonstructural hyperlordosis of the lumbar and cervical spines. The thoracolumbar pattern is uncommon and affects usually a single level with less severe vertebral wedging, but it is thought to be the most likely to progress in adulthood. Although pain is not a common medical seeking reason, it does interfere daily lives. Murray noted that 38% of the patients with Scheuermann's kyphosis had significant interference with activities of daily living because of pain compared with 21% of controls.⁵⁵ A mild scoliosis can also be found in ~30% patients. The thoracolumbar or lumbar curve is often more painful than the thoracic curve.⁵⁶

Naturally history of Scheuermann's kyphosis is lack of literature, so there are questions that still need to be answered in order to improve the recommendations for treatment. Untreated case series with progressing deformity even with neurological complications have been reported in literatures.⁵⁷⁻⁵⁹ Bracing has widely been regarded as efficacious in the treatment of kyphosis secondary to Scheuermann's kyphosis in skeletally immature patients, which is often a long-time therapeutic program till the skeletal maturing is reached. Montgomery and Erwin reviewed 39 patients with Scheuermann's kyphosis who were treated with a modified Milwaukee brace for an average of 18 months. The kyphosis before treatment is averaged 62° and after the completion of brace treatment is averaged 41°. Follow-up of >18 months after completion

of brace wear showed an average of 15° loss of correction, resulting in an average overall correction of 6°. They found that brace treatment was successful in improving kyphosis >75° in several cases.⁶⁰ Flexible deformities seemed to predict successful brace treatment. Adolescent patients can always be successfully treated by bracing. In a few patients with progressive deformity accompanied by pain that does not respond to bracing, spine arthrodesis with instrumentation is mandatory.⁶¹

Scoliosis

Usually, idiopathic scoliosis is a pain silence process in terms of lower back pain. Typical idiopathic scoliosis curves are right thoracic and left lumbar curves. A child with a pain complaint, left thoracic curve, and neurological dysfunction should be assessed for other causes of scoliosis.

There are many pathological processes that can present with scoliosis. Osteoid osteoma and osteoblastoma are the most common painful scoliosis. Sciatic scoliosis can also be found in the childhood lumbar disc herniation. Spine infection condition can present with a mild scoliosis. But under these painful scoliosis conditions, vertebral rotation and severity of scoliosis are often mild, compared with typical idiopathic scoliosis. Spontaneous curve correction can occur while the etiology of pain has been removed. Some investigators noted that although a painful scoliosis exists for long time, a compensated scoliosis would be turned into a structure scoliosis.⁶²

Congenital scoliosis and intraspinal canal anomaly-related scoliosis often present with a left thoracic curve (Figs. 101.4A and B). Improved imaging of the central nervous system with MRI has led to the diagnosis of subclinical hydrosyringomyelia (and other lesions) associated with scoliosis.^{63,64} The incidence of intraspinal anomalies of congenital scoliosis is 18–38%.^{65–67} Detailed examination and figured out atypical scoliosis radiographic curve helped the surgeon to distinguish the exact etiological classification of scoliosis. Table 101.4 listed the common indications for MR examination. Other system anomalies are also not rare in congenital scoliosis; the incidence of cardiac as well as genitourinary involvement is 10–26%⁶⁸ and 13–33%, respectively.^{69,70} Pulmonary involvement is also commonly seen in children with congenital scoliosis. The deformity alters normal pulmonary function and leads to the development of thoracic insufficiency syndrome and later the development of restrictive lung

Figs. 101.4A and B: (A) Standing AP X-ray indicated congenital scoliosis caused by T7 hemivertebra. (B) Three-dimensional reconstruction CT showed structures of T7 hemivertebra. (AP: Anteroposterior; CT: Computed tomography).

disease. Campbell recommends a detailed study of both radiographic and clinical parameters to check for lung function.⁷¹ Plain X-ray features of nonidiopathic scoliosis include curve type, widening of pedicle distance, narrow disc space, sagittal anomaly alignment, and spinal bifida occulta.

Discitis

Clinical features of discitis in childhood and early adolescence are perplexing. The exact etiology is controversial; some consider it as an infective process affecting the disc or endplates,^{72,73} while others consider it as an inflammatory condition.^{74,75} Among the pyogenic infections, terms “discitis” and “osteomyelitis” are different manifestations of the same pathological process.

The average age for diagnosis of discitis in children is ~2–8 years. The incidence of involvement of the lumbar or lumbar-sacral region represents the majority of cases (75% of patients).⁷⁶ Diagnosis of childhood discitis is difficult because the symptoms are not very specific and children face difficulty in communicating. Commonly, there are abrupt symptoms, such as abdominal pain, fever, and difficulty walking, and other decreased activity findings.^{77,78} The laboratory variables to be determined include leukocyte count, CRP, and ESR. Usually, in patients with acute disease, significant increased values of the inflammatory tests, CRP, and ESR can be observed, while in patients with chronic infections, such as tuberculosis, these tests can show normal or only slightly elevated results.⁷⁹ Blood cultures, usually

Table 101.4: Indications for magnetic resonance imaging.

<i>Pain</i>	<i>Neurological findings</i>	<i>Atypical curve pattern</i>
Back	Clonus	Left thoracic
Neck	Abnormal abdominal reflexes	Short segment (4 to 6 levels)
Radicular	Weakness	Decreased vertebral rotation
Headache	Urinary dysfunction (urinary tract infection)	Absence of thoracic apical segment lordosis
	Hyperreflexia	Rapid progression
	Asymmetric deep tendon reflexes	
	Paresthesias	
	Diminished rectal tone	
	Cavus foot deformity	
	Skin lesions	

obtained from two or three samples, are positive in 50% of the cases of unspecified discitis, and are an important guide to antibiotic therapy. In patients who have already begun taking antibiotics, the rate of identification of the pathogen decreases to around 15%. In these cases, the antibiotic therapy should be suspended for 72 hours before collecting new blood cultures.^{80,81} Biopsy of the VB and/or disc space should be considered when no organism can be identified by less invasive techniques, *Staphylococcus aureus* being the most common identified organism.

Clinical presentation of discitis can be very confused, often with unspecific symptoms, making its diagnosis difficult.⁸² The pain can distribute in hip, leg, or abdomen. The prevalence of back pain is reported to occur more commonly in children of ≥ 3 years. For the wide presentation of symptoms, delay diagnosis often arises; then a number of examinations are performed for final exact diagnosis.

Radiographs have very low sensitivity and specificity in the early stages of discitis. The earliest radiographic sign is the loss of definition and irregularity of the vertebral endplate, which can occur within 2–8 weeks of the onset of symptoms. Disc space can be narrow after 2–6 weeks. Previously, radionuclide bone scan can be performed to obtain early diagnosis of discitis. Recently, MRI has been the most useful imaging method for the investigation of discitis of the spine, particularly in the early stages. Magnetic resonance imaging has high sensitivity (96%) and high specificity (94%) for diagnosis spine infection.⁸³

The treatments of discitis in children depend largely on the exact diagnosis and conservative treatment. The principles of conservative treatment include treatment with specific antibiotics, spinal immobilization. In most cases, conservative treatment is usually sufficient, most of the patients' symptoms improving satisfactorily and

without sequelae. When laboratory tests are negative and no clinical and laboratory responses to the therapy are observed, percutaneous biopsy of the affected disc is indicated. Given the lack of specificity and poor biopsy results, the therapeutic test is indicated according to the clinical, the laboratory, and the imaging history of the cases. Some studies advocate that when discitis is suspected in children, antibiotic treatment should be empirical, based on the assessment of the probable organism and the patient's risk factors.^{84,85} Surgical irrigation and debridement is indicated while clinical infective symptoms and laboratory examination recur.

BONE TUMORS

Benign Tumors

Osteoid Osteomas and Osteoblastoma

Osteoid osteomas and osteoblastoma are the most common bone producing tumors of spine and frequently localized in posterior elements of the vertebra. These benign lesions usually occur predominantly in patients of < 20 years of age and osteoblastoma may have an older onset age distribution.^{86,87} The most common presenting symptom is pain, which can be relieved by aspirin characteristically. The pain of osteoblastoma is not as severe at night, nor is relieved by aspirin, as is the pain of osteoid osteomas. Both of these tumor types tend to occur in the thoracic and lumbar spines. For osteoid osteomas, it is small and not easy to find on routine X-ray, bone scan, CT and/or MRI can be useful in diagnosis and localization.^{88,89} Osteoblastoma and osteoid osteoma are histologically similar in many regards. The basic microscopic pattern in osteoblastoma and osteoid osteoma is bone-forming tumor containing numerous osteoblasts producing osteoid and woven bone.⁹⁰

Osteoid osteoma is predominantly marked in males, with a number of studies reporting a male-to-female ratio of 2:1 to 4:1.⁹¹ It often arises in the posterior arch region and has been widely accepted as the most common cause of pain scoliosis in adolescents. Scoliosis with less vertebral rotation and nidus located in the center of concave side is the main radiographic feature that differentiated with idiopathic scoliosis. The recommended treatment for osteoid osteoma causing disabling pain and spinal deformity is excision. The most important determinant for successful removal of the tumor is its exact localization, which can be aided with tetracycline labeling, CT,⁹² or MRI. Recently percutaneous radiofrequency thermal ablation and laser photocoagulation have been promoted as a minimally invasive treatment for osteoid osteoma located in the spine.⁹³⁻⁹⁵ However, lack of histological verification of the specimens, risks of thermal damage to the neural structures, and incomplete resection causing recurrence are the main shortcomings of these minimally invasive treatments.

Osteoblastomas are usually >2 cm and 40% locating in the spine. Compared with osteoid osteoma, osteoblastoma has more aggressive characteristics and often forms extra skeletal bone in the soft tissue. The pain is not responsive to aspirin and with less painful scoliosis. Because of its more aggressive features, spine osteoblastomas often present with symptoms related to spinal cord or root interfering. The first choice of osteoblastoma is the en bloc excision and decompression.

Aneurysmal Bone Cyst

Aneurysmal bone cysts (ABCs) are benign, highly vascular osseous lesions characterized by cystic, blood-filled spaces surrounded by thin perimeters of expanded bones. Aneurysmal bone cysts predominantly arose in children, with 60% of patients being <20 years. There is a slight preponderance for women over men.⁹⁶ Primary ABCs represent 1.4% of primary bone tumors and 15% of all primary spine tumors.⁹⁷ Almost 70% of cysts are seen in the thoracolumbar region, and <25% are seen within the cervical spine⁹⁸ and can affect more than one vertebral level. Of aneurysmal bone cysts, 60% occur in the pedicles, laminae, and spinous processes. Most patients present with symptoms of ill-defined dull pain, stiffness, swelling, and 10% patients have scoliosis or kyphosis. Neurological dysfunction is not rare for large cysts causing vertebral collapse.⁹⁹

Computed tomography typically reveals a characteristic soap bubble appearance, which represents a balloon-

ing, multilocular lytic lesion. Pathological fracture or partial VB collapse is not rare. Magnetic resonance imaging is useful in assessment of soft-tissue involvement and compromises neural elements.^{100,101} Multilocular cysts with fluid-fluid interfaces on MR T2-weighted images are highly suggestive of ABCs.¹⁰² The mainstay of treatment is surgery and most patients are cured with one or more operations. A small subset of patients with incomplete resectable, aggressive, and/or recurrent ABCs may be cured with low-dose radiotherapy (RT).

Osteochondroma

Osteochondroma is most asymptomatic in childhood. In most cases, it is presented with chronic-growth mass and secondary neurological compression symptoms. Surgical excision is the symptomatic osteochondroma choice.

Malignant Lesions

Primary malignant tumor seldom involves the spine in pediatric population. Ewing's sarcoma and osteogenic sarcoma are most common in this age population. Back pain and cord or root compressive symptoms are the common complaints of these patients.

Unfortunately, Ewing's sarcoma (ES) and osteogenic sarcoma (OS) are associated with aggressive local and metastatic spreads if left untreated or if residual disease remains after surgery. It has been widely accepted that chemotherapy or surgery alone effect cure in a few patients,^{103,104} patients are usually treated first with radiation and concomitant chemotherapy followed by surgical resection in spine.^{105,106} Some experts concluded that appropriate oncological and surgical staging is required to determine the feasibility of en bloc resection of ES and osteogenic sarcoma of the spine with acceptable margins.¹⁰⁷ The morbidity and mortality of obtaining wide and/or marginal margins in the spine are significant and therefore these operations should only be performed by experienced multidisciplinary teams.¹⁰⁸

Neuroblastoma is the most spine metastasis in children and adolescents. The prognosis is highly variable, with outcome related to age, stage, and molecular pathology. Neuroblastoma may behave in an almost benign way, with spontaneous regression in some infants, but the majority of older patients have high-risk disease, which is usually fatal. High-risk disease requires multimodality therapy including chemotherapy, surgery, and radiotherapy as well as biological and immunological treatments for optimal outcomes.

PSYCHOSOMATIC PAIN

Psychosomatic pain is a diagnosis after exclusion of any suspicious diagnosis. In some patients, symptoms seem to exceed physical examination and who might be subject to stresses from home, school, or other social factors. It has been reported that smoking or recent psychosocial stress in the family might affect the incidence of LBP in children.¹⁰⁹ Jackson et al. recommended some questions to evaluate the response of children to LBP including the following questions: "If you had to assign a color to this pain, what would it be? If you had to picture your pain as an animal, what would it be? Why? What do you do to help the pain? What can we do to help your pain?" Counseling with pediatric psychiatrists might be necessary. In case of finding any positive psychosocial history, proper intervention should be done.

- » Spinal Growth following Transpedicular Instrumentation

INTRODUCTION

Malformations of the spine represent a wide variety of conditions that may result in various deformities. Disturbance of the development occurs in the early embryologic period. The formation of the somites, the precursors of the vertebral bodies, begins at about 3–5 weeks of gestation. They begin to segment at 6–8 weeks. Normal somitogenesis may be affected by genetic or environmental factors.¹

The specific abnormality affects the further growth of the spine. Asymmetric or decreased growth may result in scoliosis, kyphoscoliosis, or a short trunk. Depending on the type of malformation Winter et al. divided the abnormalities into failure of formation, failure of segmentation, and complex (mixed) deformities.^{2,3} Figure would be ideal defects of formation include unilateral or posterior hemivertebrae. They may be fully segmented with two adjacent disc spaces, semi-segmented, or nonsegmented. Except in cases of some incarcerated vertebrae, the hemivertebra has growth potential similar to a normal vertebra, thus creating a wedge-shaped deformity that progresses during further spinal growth. Segmentation defects include bar-formations spanning one or more segments that may be located lateral, anterior, or posterior. The bar-formations usually result in a delay or cessation of growth. Asymmetric bars lead to asymmetric growth with progressive scoliosis, kyphosis, or lordosis. Mixed

deformities are frequent, often combined with abnormalities of the rib cage. Rib deformities, especially rib synostosis, may increase the scoliotic deformity of the thoracic spine.

The natural history of congenital scoliosis is well described.^{4,5} The rate of progression and the ultimate severity of the curve depend on the type of anomaly as well as the site at which it occurs. Acceleration of the progression of the scoliosis may be expected during the growth spurts. The primarily unaffected vertebrae, adjacent to the original deformity, are subject to asymmetric loads. With growth the asymmetric loads lead to a wedge-shaped deformity of these vertebrae. The rigidity of the main curve increases. Secondary curves develop to promote trunk equilibration. These curves are flexible in the beginning, but become structural with time.

EVALUATION

Clinical and Radiological

Therapeutic Considerations

The asymmetric growth based on formation or segmentation defects cannot be influenced by braces or casts. These nonsurgical treatment options induce and fix compensating curves.

Role of Observation

The only effective treatment is surgical. The indication for surgery depends on the degree of scoliosis at the time of diagnosis and the expected further progression. According to McMaster, the worst prognosis is a hemivertebra with a contralateral bar, followed by two unilateral hemivertebrae, and fully-segmented single hemivertebra.⁴ In these cases, surgery is usually required. If there is any doubt about further progression, especially in semi-segmented or incarcerated types or hemivertebrae in the upper thoracic spine, frequent radiographic follow-up is imperative. In case of significant progression surgical intervention is recommended.

The goal of treatment of congenital scoliosis is to achieve a straight spine with a physiological sagittal profile and limited growth deficit. To meet this goal early diagnosis and early surgical intervention in young children is indispensable. Surgery should be performed before the vertebrae adjacent to the hemivertebra develop an asymmetric shape, and before secondary curves become structural. In addition, the spine in very young children is highly flexible; deformity correction following resection of the hemivertebra requires little force. The risk of neurological impairment is minimal. With early and complete correction of the local deformity the development of secondary changes can be avoided. Thus, primarily healthy segments are allowed to grow physiologically. In cases of delayed treatment in older children or adults secondary structural curves need to be addressed resulting in longer fusions. For these reasons, the most favorable age for surgery is 1–5 years.

SURGICAL OPTIONS

Many different surgical procedures for treatment of congenital scoliosis have been described. Several procedures aim at preventing further progression of the deformity. Posterior fusion was the standard treatment over several decades. It may be effective if performed early before severe curves develop.^{2,3,6,7} A bilateral fusion is performed either with or without instrumentation. Most common problem of this technique is failure due to nonunion or progression of the deformity despite a solid posterior fusion. Convex anteroposterior hemiepiphysiodesis/arthrodesis is reported to achieve stabilization or even a certain correction in young children with mild curves.^{8,9} The results, however, are unpredictable and depend on the concave growth potential.

Corrective surgical techniques should aim at a maximum correction with minimum impairment of spinal growth. A precise analysis of the type of deformity and preoperative planning is imperative. Short angular deformities caused by a single hemivertebra or a monosegmental segmentation defect should be corrected completely with a short fusion. Loss of growth by a mono- or bisegmental fusion is minimal. Complex deformities, e.g. with multiple hemivertebrae, multisegmental bar formations, and accompanying rib synostosis require a more sophisticated therapy. Depending on the length of the involved spinal segment, the expected remaining growth, and possible rib cage abnormalities, nonfusion techniques, if necessary in combination with correction and short fusion of the apex of the deformity, may be applied.

PREOPERATIVE PLANNING

Preoperative radiographic examination includes X-rays of the whole spine and the region of the deformity in a standing position. If necessary, bending films are obtained to assess flexibility especially of the secondary curves. Computed tomographic (CT) scans with three-dimensional reconstructions are indispensable to evaluate the shape and location of the hemivertebra and the adjacent vertebrae, and to provide information on bar formations or ribs synostoses. The size and diameter of the pedicles are measured to select proper size of the screws. Three-dimensional reconstructions are helpful for surgical planning especially in mismatched abnormalities of the anterior and posterior structures.

Congenital malformations of the spine are frequently accompanied by spinal dysraphism and genitourinary and cardiac problems.^{10,11} Magnetic resonance imaging (MRI) of the spinal cord is obligatory to evaluate for malformations that may require neurosurgical intervention. Ultrasound screening should be performed to exclude genitourinary and cardiac changes. Briefly more on associated congenital malformations with the incidences. Staging of neurosurgical procedures in congenital scoliosis or whether it can be done in one stage. Controversies regarding whether to operate on all intraspinal abnormalities should be addressed.

HEMIVERTEBRA RESECTION

In the case of hemivertebrae resulting in congenital scoliosis the resection of the hemivertebra resection offers an efficient therapy. In the great majority of cases at the thoracolumbar spine a single posterior approach is

sufficient for a complete resection of the hemivertebra with fusion of the adjacent segments. Only at the cervical spine a combined anterior and posterior procedure is required due to the vertebral arteries. At the lumbosacral junction, an additional anterior approach may facilitate complete resection of the body of the hemivertebra.

Hemivertebra resection was first described by Royle in 1928.¹² In the beginning poor results and a high rate of complications such as pseudarthrosis, kyphosis, and neurological deficits were discouraging. In 1979, Leatherman reported on improved results in a larger series of hemivertebra resection in a two-stage procedure.¹³ Further reports on resection of hemivertebrae by a combined anterior and posterior approach followed. Closing of the wedge after resection was achieved by casts and braces that were applied for about 6 months,¹⁴⁻¹⁷ by sutures or wires,^{18,19} or by a posterior hook-rod instrumentation.^{14,16,20-25} More recently reports on hemivertebra resection by a single posterior approach were published.²⁶⁻⁴⁰ Pedicle screws have been demonstrated to be safe and efficacious even in very young children.⁴¹

Posterior Hemivertebra Resection: Surgical Technique

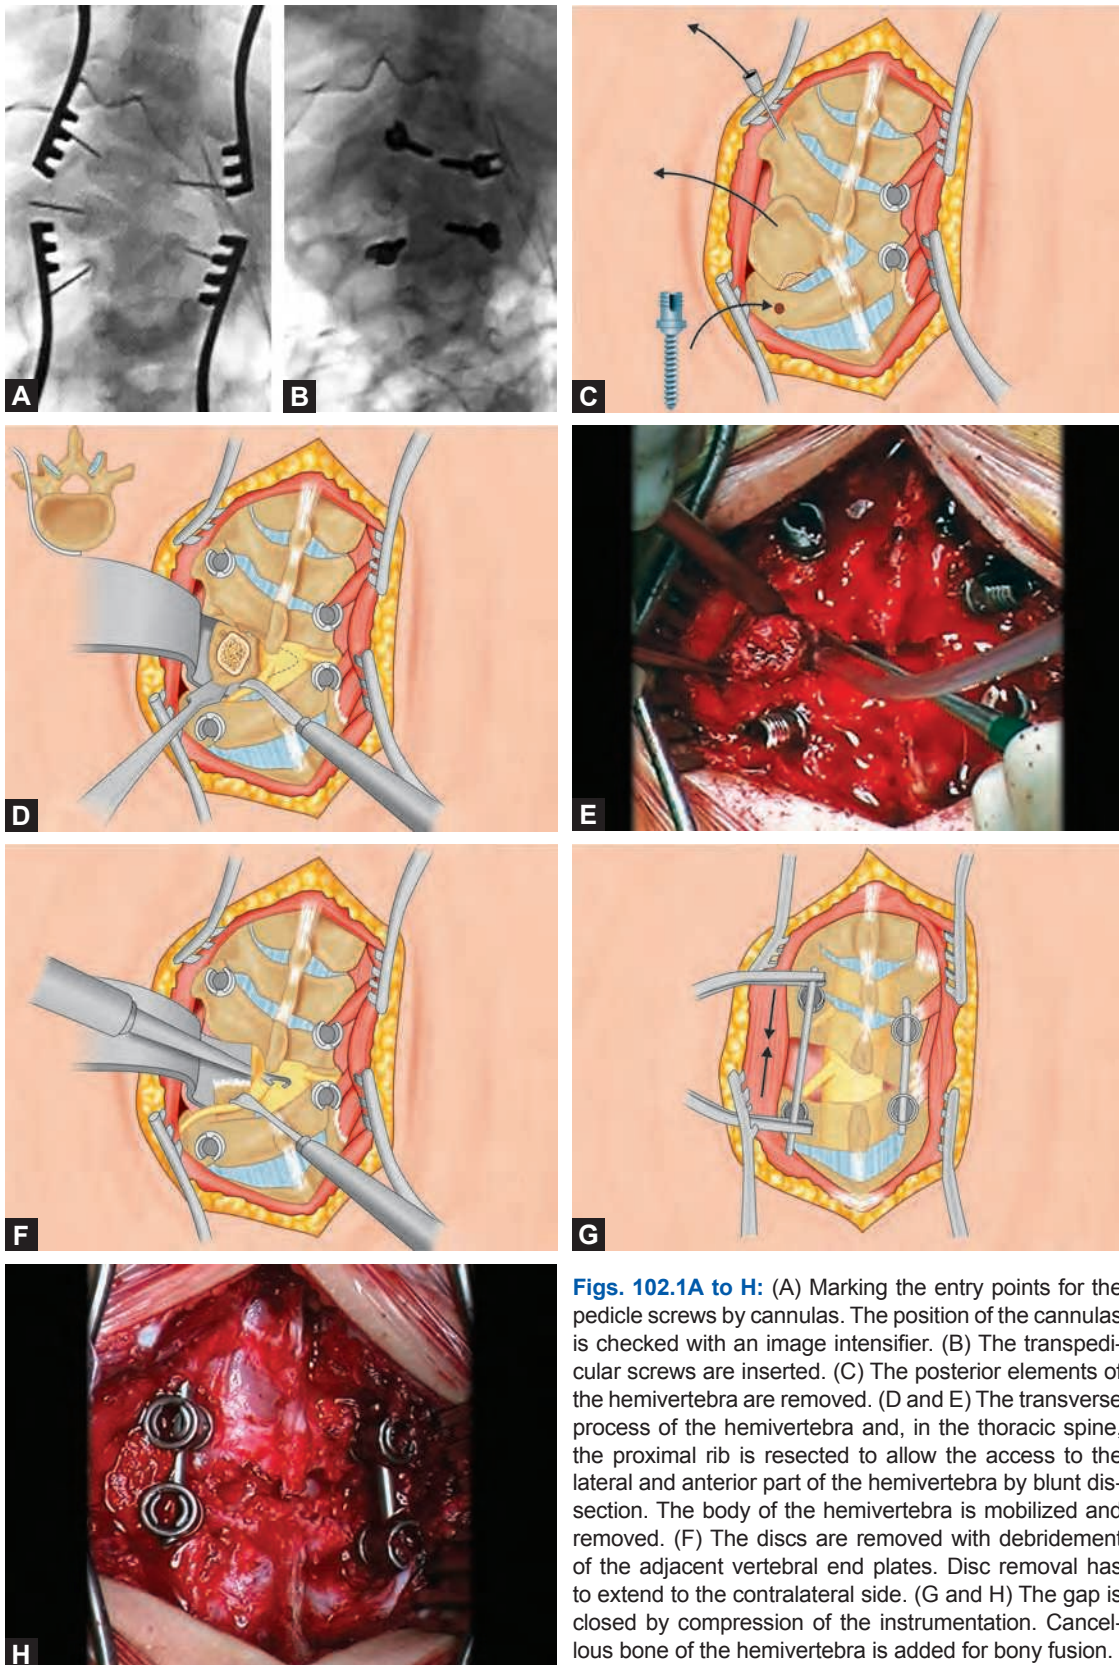

The following technique of hemivertebra resection was introduced by Jürgen Harms in 1991.²⁸ The technique is especially suitable in young patients with mobile segments around the hemivertebra. It offers several advantages as follows:

- The complete resection of the hemivertebra is performed by means of a less invasive single posterior approach.
- An excellent correction in both the frontal and the sagittal planes is achieved.
- The transpedicular instrumentation ensures a high stability and allows for a short fusion.
- Early mobilization is possible that is especially important in young children.
- The spinal cord is visible during the correction maneuver that minimizes neurologic risk.
- The technique is applicable in very young children as early as 1 year of age.

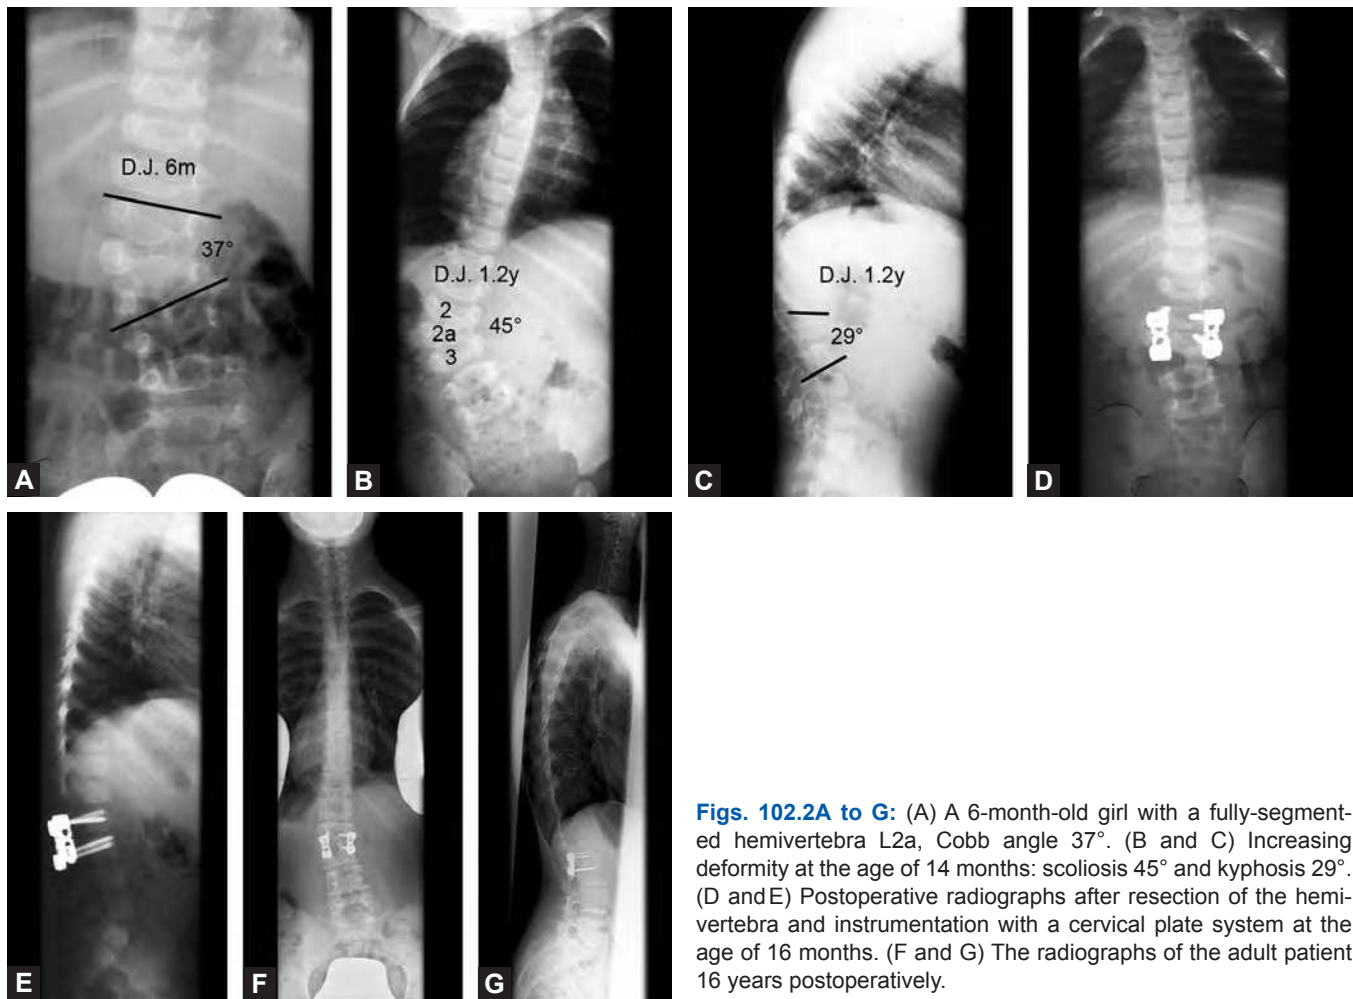

Patients are placed in prone position. The posterior elements of the spine are carefully exposed at the affected levels, including the lamina, the transverse processes, the facet joints, and, in the thoracic spine, the rib head on the convex side. This exposure should meticulously maintain the periosteum at the bony structures except at the area,

where fusion is planned. The entry points for the planned pedicle screws are marked by cannulas and their position checked by an image intensifier in an anteroposterior view (Fig. 102.1A). This identification of the pedicles is particularly important in cases with mismatched abnormalities of the anterior and posterior structures. The landmark for the entry point for the pedicle screw in the lumbar region is the base of the transverse process at the lateral border of the superior articular facet. In the thoracic region, the entry point is at the superior margin of the transverse process slightly lateral to the lower lateral edge of the articular facet. After verifying the correct position of the cannulas the bone at the pedicle entry points is opened with a sharp awl or small burr. A 1.5- or 2.0-mm drill is incrementally advanced through the pedicle into the vertebral body. The drill-holes are marked with Kirschner-wires. Their correct position is checked with an image intensifier. After tapping, the screws are inserted (Fig. 102.1B). Screw diameter depends on the size of the pedicle. In children <5 years of age 3-mm screws are usually appropriate.

The posterior elements of the hemivertebra are removed. Resection includes the lamina, the facet joints, the transverse process, and the posterior part of the pedicle (Fig. 102.1C). The spinal cord and the nerve roots above and below the pedicle of the hemivertebra are identified. In the thoracic spine, the rib head and the proximal part of the extra rib at the convex side are resected as well. After resection of the transverse process and the rib head, the lateral and anterior part of the hemivertebra at the convex side can be exposed by blunt dissection. This exposure is retroperitoneal in the lumbar spine and extrapleural in the thoracic spine. A blunt spatula is inserted to protect the anterior lying vessels. The remnants of the pedicle are removed and the posterior aspect of the vertebral body of the hemivertebra is exposed. This is facilitated by the fact that the hemivertebra lies far laterally on the convex side, while the spinal cord is usually shifted to the concave side. The discs adjacent to the hemivertebra are incised and the body of the hemivertebra is mobilized and removed (Figs. 102.1D and E). The rest of the disc material at the upper and lower vertebra is removed completely with debridement of the vertebral end plates to bleeding bone. This meticulous disc removal has to extend to the contralateral side (Fig. 102.1F). In cases of pronounced kyphosis, an anterior column support, using a titanium mesh cage, may be added to create a fulcrum to achieve lordosis. The instrumentation is completed and compression is applied on the convex side until the gap, which remains after the

Figs. 102.1A to H: (A) Marking the entry points for the pedicle screws by cannulas. The position of the cannulas is checked with an image intensifier. (B) The transpedicular screws are inserted. (C) The posterior elements of the hemivertebra are removed. (D and E) The transverse process of the hemivertebra and, in the thoracic spine, the proximal rib is resected to allow the access to the lateral and anterior part of the hemivertebra by blunt dissection. The body of the hemivertebra is mobilized and removed. (F) The discs are removed with debridement of the adjacent vertebral end plates. Disc removal has to extend to the contralateral side. (G and H) The gap is closed by compression of the instrumentation. Cancellous bone of the hemivertebra is added for bony fusion.

Figs. 102.2A to G: (A) A 6-month-old girl with a fully-segmented hemivertebra L2a, Cobb angle 37°. (B and C) Increasing deformity at the age of 14 months: scoliosis 45° and kyphosis 29°. (F and G) The radiographs of the adult patient 16 years postoperatively.

resection, closes completely (Figs. 102.1G and H). Cancellous bone (bone material from the hemivertebra) may be added to facilitate bony fusion. The neural structures must be controlled and protected at all times during the resection of the hemivertebra as well as during the corrective maneuver.

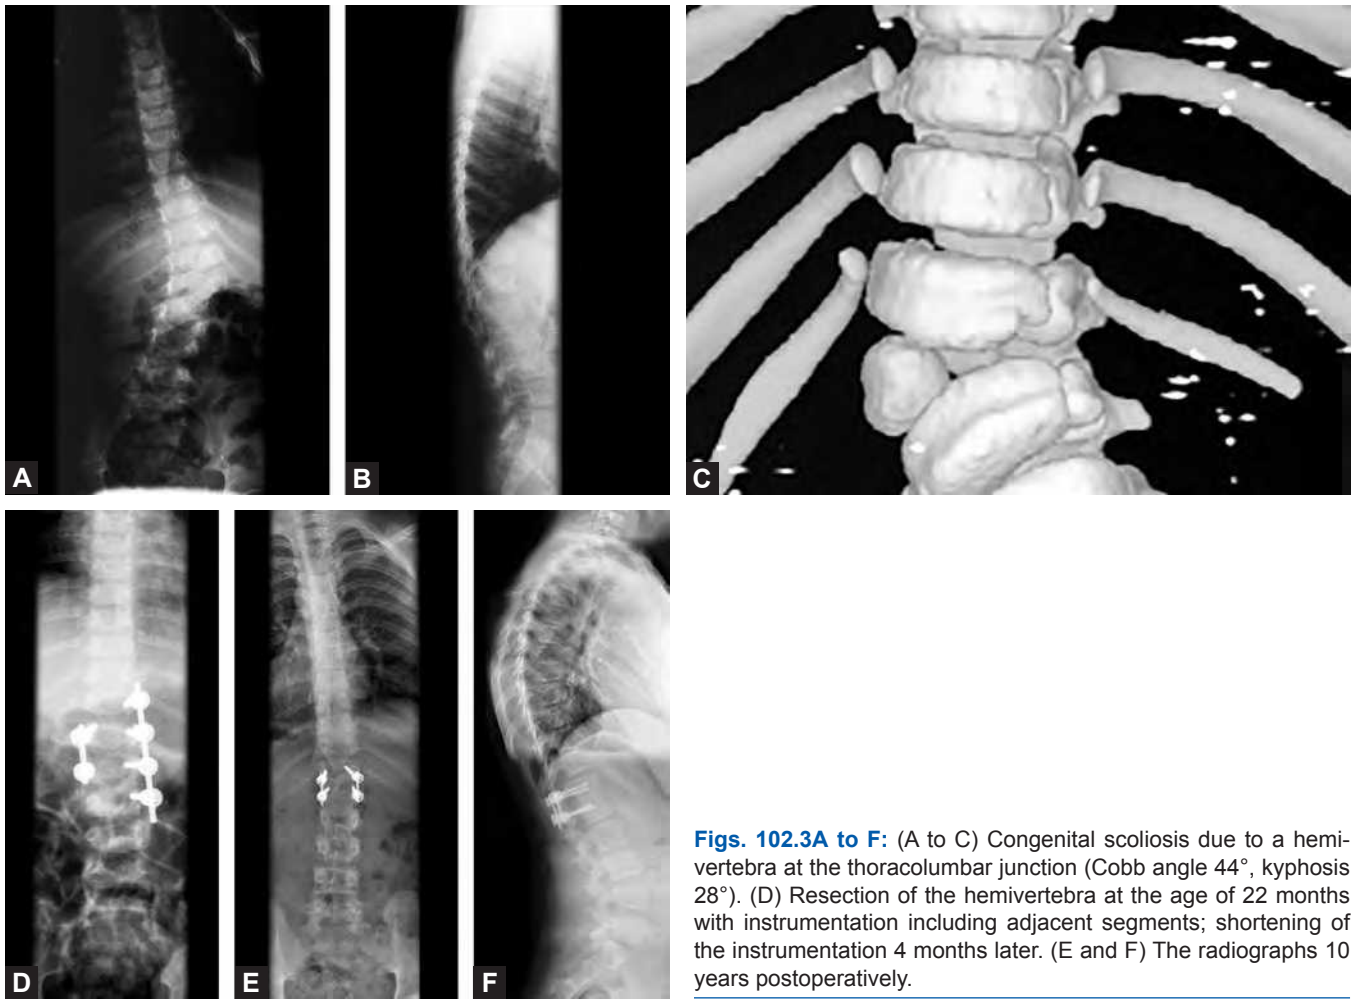

In cases of single hemivertebrae without bars, rib synostosis, or other major structural changes of the neighboring vertebrae, only the two vertebrae adjacent to the resected hemivertebra are fused (Figs. 102.2A to G). If a high amount of compressive force is necessary to correct the deformity, especially in cases with pronounced kyphosis, one or two additional segments should be permanently or temporarily included into the instrumentation to avoid overloading of the pedicles with subsequent pedicle fracture. If a temporary instrumentation is planned, the exposure of these additional vertebrae should be performed very carefully with preservation of the periosteum and the facet

joints. Three months after primary surgery, the instrumentation is shortened to the fused segments. The temporarily instrumented segments are released to regain mobility (Figs. 102.3A to F).

Spinal monitoring is essential for maximum safety especially during the correction maneuver.

Posterior Spinal Osteotomy: Surgical Technique

In patients with bony fusion adjacent to the hemivertebra, especially in older children or adults, or in patients with a contralateral bar-formation, a complete osteotomy of the spine is required to achieve a sufficient correction.^{32,42} In addition to the convex dissection at the apex with resection of the hemivertebra, an additional exposure of the synostosed vertebrae at the concave side via the posterior approach is performed. This access to the concave lateral

Figs. 102.3A to F: (A to C) Congenital scoliosis due to a hemivertebra at the thoracolumbar junction (Cobb angle 44° , kyphosis 28°). (D) Resection of the hemivertebra at the age of 22 months with instrumentation including adjacent segments; shortening of the instrumentation 4 months later. (E and F) The radiographs 10 years postoperatively.

wall of the spine has to be very oblique, as the spinal cord is usually shifted to the concavity and due to the rotation of the apical vertebrae.

In these patients, pedicle screws are placed in at least two segments above and below the planned osteotomy. In the thoracic spine, a bilateral costotransversectomy at the apex is performed. The proximal parts of the ribs including the rib heads are removed. In case of rib-synostosis at the concave side, a wide resection of the synostosed ribs is required to gain the very oblique access to the lateral wall of the vertebral body. The lateral aspect of the vertebrae is exposed by blunt dissection. A laminectomy is performed at the apex, including the lamina of the hemivertebra and partially the adjacent laminae, including a wide wedge of the synostosed laminae in case of defects of segmentation. The joint facets are removed, and the spinal cord and the nerve roots are identified.

The pedicles at the apex are removed. Then the wedge-shaped resection of the vertebral body is performed. The wedge comprises the body of the hemivertebra or, in segmentation defects, a wedge according to the desired angle of correction. The major portion of the vertebral body is usually removed from the convex side; however, to achieve mobility, the bar at the concavity must be cut or resected as well (Fig. 102.4). This part of the surgery may be demanding, as the spinal cord is usually tight at the concave pedicles. Thus, the approach to the concave part of the vertebral body has to be very oblique. To avoid bulging during compression, the posterior wall must be completely removed. The bilateral resection entails a complete disruption of continuity of the spine. It is therefore essential to place at least one rod on the contralateral side for stabilization during the osteotomy. When the resection is complete, correction is performed by closing

Fig. 102.4: Resection of a wedge-shaped apical vertebral body. One rod is in place to avoid a dislocation.

the gap by compression via the instrumentation. During this maneuver, the spinal cord must be thoroughly controlled to avoid any impingement. Spinal cord monitoring is imperative. Especially in kyphotic cases an anterior spacer is inserted that acts as a hinge for correction. The height of the spacer is ideal when after complete correction the length at the spinal cord is slightly shortened. Bone material from the vertebral body is added posterolateral for fusion.

Hemivertebra Resection at the Lumbosacral Junction

While in the thoracic and lumbar spine the resection of a hemivertebra via a single posterior approach is usually unproblematic, it may be more demanding at the lumbosacral junction. The access to the body of the hemivertebra is complicated by the iliac crest and the sacral ala, especially in male patients. In these cases, a combined approach starting with an anterior resection of the vertebral body is advantageous. A preoperative imaging and a meticulous intraoperative dissection of the iliac vessels is necessary (Figs. 102.5A to D).

Postoperative Management

Patients are mobilized within the first postoperative week. A brace is worn for usually 12 weeks. Radiographs are taken at 2 weeks, 3 and 6 months postoperatively. Radiographic examinations are performed once a year until

the end of growth. The implants should be left in place until the patients are skeletally mature to avoid the risk of increasing deformity despite bony fusion.

Hemivertebra Resection in the Cervical Spine

Congenital scoliosis due to a hemivertebrae is rare in the cervical spine. The deformity is often associated with additional anomalies like congenital block vertebrae (Klippel-Feil syndrome) and congenital scoliosis in the thoracic and lumbar spine.⁴³ Most patients present with restriction of neck motion, head tilt or torticollis, and asymmetric shoulder level. Especially in patients with Klippel-Feil syndrome, there is little possibility for compensation of scoliosis in the frontal plane. In an effort to keep the head straight with the eyes in a horizontal line, most patients develop severe compensatory curves in the thoracic region (Figs. 102.6A and B).

Surgical therapy therefore should be performed early in patients with severe disfiguring deformity or patients with proven or expected deterioration. Hemivertebra in the cervical spine (except C7) requires a combined posterior and anterior approach due to the course of the vertebral artery. A meticulous preparation of the spinal cord, the nerve roots, and the vertebral arteries is imperative. After complete resection of the hemivertebra the correction is achieved by closing the gap with anterior or posterior compression instrumentation (Figs. 102.7A to D).⁴⁴

Growth Guiding Techniques

Children with multisegmentation defects or combinations of hemivertebrae, contralateral bar formations, and rib synostosis are the most challenging group of patients. These spinal deformities are usually rapidly progressive with a poor prognosis. Correction by means of osteotomies and fusion would require a long instrumentation, and may require inclusion of the structural secondary curves. The multisegmental instrumentation with fusion would induce a substantial growth deficit.

To address this problem and to minimize the growth deficit, a growth guiding or distraction device may be helpful. Possibilities are growing rod techniques, sliding rod systems, or, in case of predominant rib cage deformities, a rib distracting device.^{45,46} Depending on the type of deformity, a combination of different surgical procedures may be used

Figs. 102.5A to D: (A to C) A 12-year-old girl with an asymmetric butterfly vertebra at L5. Secondary lumbar curve of 50°. A precise imaging of the iliac vessels is necessary for planning the anterior approach. (D) Postoperative radiograph after the anteroposterior resection and fusion of L4 to S1. Spontaneous correction of the lumbar curve to 22°.

Figs. 102.6A and B: (A) A 2-year-old boy with hemivertebrae C3a and C7a at the left side. The thoracic spine is still straight. (B) Same boy at the age of 14 years: increasing deformity at the cervical spine and the cervicothoracic junction, compensatory structural curve of 79° at the thoracic spine.

Figs. 102.7A to D: (A and B) Cervical scoliosis in an 8-year-old child due to a double hemivertebra (C2a + C4), atlanto-occipital synostosis, and block vertebra C5-C6. Scoliosis of 32°, head tilt 19°. (C and D) The radiographs 5 years after hemivertebra resection C4 by a posterior-anterior-posterior approach. Scoliosis of 7°, head tilt 5°.

to optimize the results. Hemivertebra resection with osteotomies and short fusion provides an excellent correction of the deformity at the apex. A supplementary growth-directing instrumentation may be added to guarantee normal growth of the adjacent spine. Such a combination of different procedures may achieve the optimum result with a straight spine and a minimal growth deficit (Figs. 102.8A to E). The key element of all growth preserving techniques is a very careful surgical technique with preservation of the periosteum and adjacent soft tissues. Injuries of the vertebral joints and very stiff implants increase the tendency to premature fusion. We have to be aware that the initially included spinal segment will be fused after the growth-guiding procedure.

SPINAL GROWTH FOLLOWING TRANSPEDICULAR INSTRUMENTATION

Transpedicular screws allow for the most stable fixation of vertebrae in spine surgery. Especially in very young patients where the connection between the posterior structures and the vertebral bodies via the neurocentral synchondrosis is still weak, the pedicle screws allow for a reliable fixation. A reliable fixation is fundamental for sufficient correction, short fusion, and early mobilization. The transpedicular instrumentation is able to transmit a high amount of compression force to the vertebral body to close the gap after resection of a hemivertebra.

However, crossing the neurocentral synchondrosis by transpedicular screws in very young children may give

Figs. 102.8A to E: (A) A 3-year-old girl with a congenital scoliosis at the cervicothoracic junction (hemivertebrae C7 and T3) and thoracic scoliosis. (B to D) Radiographs postoperatively, 12 months postoperatively, and after distraction. (E) Four years after the initial surgery with an additional screw and further distractions.

Fig. 102.9: Magnetic resonance imaging 7 years after transpedicular instrumentation in a 22-month-old child (same patient as in Figs. 102.3A to F): no stenosis of the spinal canal.

rise to objections concerning further growth of the vertebrae and the width of the spinal canal. Since 1991, several hundred transpedicular screws were inserted in 1- and 2-year-old children. None of these children developed neurological deficits during further growth. Magnetic resonance imaging and CT scans showed no spinal stenosis (Fig. 102.9).^{41,47} There was vertebral growth despite the instrumentation in longitudinal as well as in vertical direction. The posterior instrumentation may act as a tether leading to increasing lordosis (Figs. 102.10A to C).

CONCLUSION

Treatment of congenital scoliosis in the growing spine is a challenging task. The goal of the treatment is to achieve a straight spine with a minimal growth deficit at the end of growth. Due to the wide variety of formation and segmentation failures, therapy for each patient has to be chosen individually depending on the type of deformity, the severity, and the expected progression. Planning of the therapy requires a precise imaging to classify the deformity, and a profound knowledge of the natural history of the spinal anomaly. Different surgical techniques are available like hemivertebra resection, spinal osteotomies and bar resections, growth guiding and distracting techniques. For the individual patient a combination of different techniques or a staged procedure may be useful to achieve the optimal result.

These are the key points for successful treatment:

- Maximum correction at the apex of the deformity in the frontal and sagittal plane
- Fusion as short as possible to minimize growth deficit
- High stability for early mobilization
- Early correction to avoid the development of secondary structural curves.

In case of a single hemivertebra without any additional anomalies resection of the hemivertebra is likely curative. With a complete correction and a short fusion, we may expect a normal further growth of the infused spine. The monosegmental fusion imposes no restrictions.

Figs. 102.10A to C: Transpedicular instrumentation at the age of 2 years, 8 years, and 14 years: there is growth of the vertebral bodies, with longitudinal growth anteriorly. The posterior tether leads to increasing lordosis.

In cases with severe combinations of formation and segmentation defects and possible rib cage deformities, the final result depends on the growth potential of the spinal segments. The residual growth should be used optimally. However, a certain amount of growth deficit compared to a normal spine may be inevitable.

For all patients with congenital deformities frequent follow-up evaluations are mandatory until the end of growth.

INTRODUCTION

Neuromuscular diseases are heterogeneous between and within diseases and are due to a vast number of pathologies involving the brain, spinal cord, peripheral nervous system, and muscle. The prevalence of spinal deformity is typically proportional to the severity of neurologic impairment. It may range from 5% in the spastic diplegic cerebral palsy child to 100% in the young child with spinal cord injury. Progression is common to the natural history of scoliosis in most neuromuscular diseases.^{1,2} Conservative treatment with bracing and/or wheelchair modifications is only temporary and does not prevent curve progression. Progression often also occurs after skeletal maturity.³ Curvatures over 60° begin to affect sitting and standing balance, head control, as well as pulmonary function. Pelvic obliquity may also occur and is secondary to the scoliotic deformity extending to the pelvis. Sagittal plane deformities can occur in combination with scoliosis or in isolation in neuromuscular disease. Isolated hyperlordosis and hyperkyphosis is less common than scoliosis, but can also cause seating problems and pain especially when >70°. ^{4,5}

Surgical management is warranted to improve the quality of life in neuromuscular disease. It is indicated in progressive curves when the child is not tolerating seating

(in nonambulators) or standing (in ambulators), or if the natural history of the neuromuscular disease predicts progression associated with the deterioration of pulmonary status. Surgery may also be indicated to alleviate pain or to correct pelvic obliquity prior to correcting a concomitant hip dislocation.

PRINCIPLES AND GOALS

The principles and goals for treating neuromuscular scoliosis are vastly different than idiopathic scoliosis. Children with neuromuscular disease often have multiple comorbidities, and a greater risk of mortality. The risk of the natural history of the neuromuscular disease must be weighed against the risk of the natural history of scoliosis progression for that specific neuromuscular condition and the risk of surgical intervention for the individual patient. How to balance these considerations mandates that the surgeons have an in-depth understanding of natural history of the neuromuscular condition and the risk of scoliosis progression for each neuromuscular condition as well as specific concerns impacting the patient and/or caretaker.

Despite the heterogeneity of neuromuscular conditions that are associated with neuromuscular scoliosis, there are a number of common issues to the treatment of these children:

- The importance of etiology in the natural history of the disease and the scoliosis
- Presence of comorbidities
- Nonoperative treatment is generally unsuccessful
- Rapid curve progression that may occur earlier in life
- Rigid curvatures
- Frequent pelvic obliquity
- Long C-shaped curvatures
- Loss of sitting or standing balance
- Concurrent hyperlordosis and hyperkyphosis
- Higher surgical risk/complications.

ETIOLOGY

Whether the neuromuscular disease originates from pathology involving the upper or lower motor neurons, the peripheral nervous system, or the muscle, neuromuscular scoliosis is a consequence of muscle imbalance. It occurs in patients with a wide variety of neuromuscular diseases that include cerebral palsy, poliomyelitis, myelomeningocele, spinal muscle atrophy, muscular dystrophies, myopathies, and infectious, metabolic and traumatic encephalopathy. Neonatal and prenatal causes of cerebral palsy are mainly related to prematurity and birthing problems, leading to various severities of deformity patterns. Postnatal trauma, metabolic encephalopathy, infections, toxicities, child abuse, and closed brain injury are often left with neurologic defects and in severe cases quadriplegic involvement significant to spinal deformities. Knowing the exact etiology is not always critical to care for child with neuromuscular disability or deformity; however, it is extremely valuable to understand whether the neuromuscular lesion is static or progressive. There are considerable concerns for the patient in terms of worsening sitting balance, respiratory function, rib-to-pelvic painful impingement, and loss of upper extremity function in striving to remain upright. The cause of scoliosis is directly related to the severity of the neurological deficit. It is not exactly clear which component of neurological control is directly responsible for the spinal curvature; nevertheless, the most severely involved neurologically deficient patients have most severe scoliosis. Poor muscle control in the growing spine is the primary etiology, with spasticity, muscle weakness and poor balance are also substantial contributing factors.

NATURAL HISTORY

In general, the greater the severity of the neuromuscular involvement, the greater the prevalence, the earlier the onset, and the greater the risk of more rapid progression of the

scoliosis. The scoliosis or sagittal plane spinal deformity in general is due to muscle imbalance of low or high tone and abnormal postural reflexes. Its frequency ranges from 25% to 90% depending on the associated disorder.⁵ Curve patterns are most commonly lumbar or thoracolumbar with associated pelvic obliquity. Scoliosis in the patient with neuromuscular disease is rarely present in early childhood, and when it is present, it is typically flexible and lacks significant structural components. On occasion, a structural curve may occur at an early age of 2 or 3 years. Treating physicians must be aware that these curves may advance fairly rapidly in magnitude and stiffness for these patients (Figs. 103.1A and B). The natural history of both the neuromuscular disease and the scoliosis within each disease is critically important for the surgeon to understand the impact that the scoliosis will have on the child's longevity and quality of life. In addition, the natural history of the disease impacts the associated comorbidities, surgical timing, and the subsequent risks associated with surgery.

PATIENT ASSESSMENT

With the consented decision of the family to proceed with the surgery, adequate preoperative workup must ensure that all medical conditions are under maximum medical management. All children with neuromuscular conditions should have a detailed preoperative assessment. Patients with neuromuscular disease often have associated medical comorbidities that correlate strongly with postoperative complications and include gastroesophageal reflux, restrictive lung disease, aspiration pneumonia and reactive airway disease, heart disease, poor nutrition, the presence of a seizure disorder, and low bone mineral density. These should be identified in the medical history and preoperatively, and comanaged medically.⁶

Physical examination should assess sitting and standing balance, pelvic obliquity, curve stiffness, and the spinal deformity's coronal, sagittal, and rotational components. The orthopedist should also evaluate for the coexistence of hip subluxation or dislocation. Curvatures that are stiff in both the coronal (scoliosis) and sagittal planes (severe hyperlordosis and hyperkyphosis) may require anterior^{6,7} release or preoperative traction.⁸ The side-bending test is helpful for assessing coronal plane stiffness (Fig. 103.2). Sagittal plane stiffness should also be assessed by seeing if kyphosis will reduce in the supine position over a bolster and assessing the flexibility of hyperlordosis by hyper-reflexing both hips and the pelvis in the

Figs. 103.1A and B: This is a boy with quadriplegic cerebral palsy who developed progressive scoliotic curve of 7° to over 90° within 18 months.

Fig. 103.2: Side-bending test for assessing coronal plane stiffness.

supine position. If the deformity cannot be reduced in either plane, anterior discectomy should be considered. It is important to assess and distinguish the coexistence of a hip flexion contracture and adduction contracture in the high-tone neuromuscular conditions (e.g. cerebral palsy) with spinal deformity. This can be done by stabilizing the pelvis in a neutral position (flexing the opposite hip to level the pelvis to detect hip flexion contracture and assessing hip abduction with the pelvis in neutral obliquity). If these contractures are present, the parents should be warned

that muscle releases may be necessary 4–6 months after spinal surgery. The surgeon must also assess the need for fusing to the pelvis. In the cerebral palsy patient, this is almost always necessary to prevent distal extension (late pelvic obliquity) of a curvature fused to short. Patients with poor “righting reflex” (ability to center the head over the center of the sacrum) should be fused from T1 to the pelvis. Standing or sitting anteroposterior (AP) and lateral radiographs are important not only to measure curve magnitude, but to look at balance. Coronal and sagittal bending films, and traction films are operator-dependent and if done correctly can give important information about curve flexibility. Finally, the child should also have a detailed neurological examination that includes sensory and motor testing, and reflexes including abdominal reflexes to establish baseline neurological function and the need to look for any undiagnosed intraspinal pathology such as tethered cord or syringomyelia.

PREOPERATIVE CONSIDERATIONS/COMORBIDITIES

Patients with neuromuscular disease often have associated medical comorbidities that correlate strongly with postoperative complications and include the presence of cardiac disease, gastroesophageal reflux, restrictive lung disease, reactive airway disease, aspiration pneumonia, poor nutrition, the presence of a seizure disorder, and low bone mineral density. Preoperatively, these should be identified and medically comanaged.⁶

Nutritional and Gastrointestinal Problems

Children with neuromuscular disorders may have poor oral motor function and therefore poor nutritional intake. In addition, some children may have poor intestinal absorption. Poor nutritional intake may lead to higher infection rates and low bone mineral density in patients with neuromuscular disease causing poor surgical outcomes. In children with cerebral palsy and other spastic neuromuscular conditions, increased spasticity may increase nutritional requirements causing weight loss. Gastrostomy-tube (G-tube) placement is often helpful for long-term nutritional management. Gastroesophageal reflux is common in children with neuromuscular disease and may lead to chronic esophagitis resulting in failure to thrive as well as chronic aspiration leading to pneumonia. Some children may benefit from funduplications and/or jejunal feedings to prevent reflux. The involvement of the nutritionist and gastroenterologist is important to optimize preoperative nutrition and minimize postoperative complications. There are no specific nutritional criteria that would exclude surgical intervention; however, children with no subcutaneous fat, poor food intake, and poor body weight for height ought to have nutrition enhanced by feeding supplementation, including that of nasogastric tube feeding. Finally, there is no good evidence of a particular nutritional level preoperatively that matters if aggressive postoperative nutrition is carried out.^{9,10}

Pulmonary

Pulmonary disease in the child with neuromuscular disease falls into two primary categories: reactive airway disease and restrictive lung disease. The former is usually a result of gastroesophageal reflux and chronic aspiration of gastric contents and/or saliva. In addition to the management of gastroesophageal reflux, tracheal diversion may be necessary to prevent aspiration of saliva.

Restrictive lung disease is more common in flaccid neuromuscular disease [see special considerations under: Duchenne muscular dystrophy and spinal muscular atrophy (SMA)]. Early surgical management and ventilator treatment may help delay respiratory failure in these children. Comanagement with a pulmonologist is imperative to preoperative management.

Cardiac

Preoperative cardiac workup should be considered in all children with neuromuscular disease with curvatures $>80^\circ$ and in children with, Duchenne muscular dystrophy, Friedreich ataxia, and certain myopathies.

Endocrine

At our institution, some children with upper motor neuron disease have been discovered to have deficiencies in thyroid hormone, cortisol, while others may have more significant endocrinopathies (e.g. panhypopituitarism). If clinically indicated, these should be investigated and addressed prior to any surgical intervention of the spinal deformity.

Neurologic

Many children with neuromuscular disease have seizure disorders. Adequate seizure medication levels should be obtained prior to surgery and comanaged by the neurologist. In addition, some patients with neuromuscular disease, especially those with myelodysplasia have ventricular-peritoneal shunts. Intraventricular shunts should be checked with radiographs and computed tomography (CT) scan to make sure that they are not broken and are functioning (Fig. 103.3). If the shunt is still needed, it should be checked by the neurosurgeon preoperatively.

Fig. 103.3: Malfunctioning ventricular-peritoneal shunt found to be broken.

Bone Density

A final preoperative consideration is the bone density of the child with neuromuscular disease undergoing spinal fusion. The child who is poorly nourished, nonambulatory, and on seizure medication is at greatest risk. In the child with low bone density, instrumentation may be difficult with a possibility of sublaminar wires cutting out and pedicle screws pulling out of osteopenic bone. Children on seizure medications should have vitamin D, calcium, phosphorus, and alkaline phosphorous levels checked. Nonambulatory children with a history of low-impact type long-bone fracture should undergo bone density measurement using dual-energy X-ray absorptiometry (DEXA scan). Children with measurements two or more Z scores below the mean should be considered for treatment with bisphosphonate therapy such as with intravenous (IV) pamidronate.

TREATMENT PRINCIPLES

Bracing

Nonoperative treatments have not had any documented impact on the progression or eventual outcome of neuromuscular spinal deformity. It is important, nevertheless, to address the conservative modalities that may provide some temporary beneficial use in maintaining upright sitting.

Seating adaptations such as hip guides and offset chest lateral seat supports may temporarily improve sitting in wheelchairs or other seated devices. This is especially helpful in very young children with flexible curvatures. Hip guides serve to capture the pelvis while offset chest laterals with one on the convex side at the apex of the curve and another one placed just below the axilla on the concave side of the curve serves as a three point “corrective” force to hold the patient upright (Fig. 103.4).

Neuromuscular scoliosis has not shown beneficial response to bracing demonstrating no change in the rate of progression or final outcome of the magnitude or stiffness of the spinal deformity.¹ Some children have been braced for as long as 14 years, kept in brace wear for 23 hours a day in facilities with exceptional documentation and still developed typical scoliosis of the same magnitude and stiffness.¹¹ Higher magnitude yet still flexible curves in younger children may require the additional support of bracing in order to delay surgery while still maintaining upright sitting posture. A soft thoracolumbosacral orthosis (TLSO) jacket that is well padded to prevent any skin

Fig. 103.4: Hip guides and offset chest laterals placed one of the apex convexity and another placed below the axilla on the concavity serve as a three-point corrective positioning force to keep the boy upright.

Fig. 103.5: Bracing may provide upright positioning support yet have little to no effect on curve progression.

breakdown can be easily applied and removed (Fig. 103.5). Caretakers should be educated that the orthosis will not benefit the structural scoliosis curve, therefore should be used only at times when it is providing children direct functional benefit such as when they are in their wheelchair. In fitting these children into their wheelchairs with the

brace in place, wheelchair modifications may be necessary when the children are in the brace yet the chair may not fit properly without the brace. In such cases, the family and caretakers may need to decide if they want the child in the brace almost entirely when seated, or if they want to use it only for specific seating aside from in the wheelchair. Problems with bracing may include discomfort in warm weather, pressure sores, and restriction of the child's breathing ability. Another restrictive concern may occur during feeding, particularly in children who are tube-fed and have gastroesophageal reflux. In these incidences, the orthotic may be loosened or simply removed during and for an hour period after feeding. It is also important that the family's expectations be clearly addressed as to not gain the false hope that the orthotic use will alter the rate and eventual progression of the spinal deformity.

Surgical Treatment

The principles of spinal deformity correction in neuromuscular scoliosis are to: (1) correct pelvic obliquity by leveling the pelvis with the sitting or standing surface, (2) restore trunk balance, (3) center the head over the trunk and pelvis, (4) restore sagittal balance (lumbar lordosis and thoracic kyphosis including the correction of anterior and posterior pelvic tilt, respectively), (5) maximize segmental fixation in the face of what is often osteoporotic bone, and (6) minimize operative time in this patient population who often have multiple comorbidities and who are at greater risk for wound infection. Rotational correction is less important unless the rotational deformity is affecting pelvic or trunk balance.

Posterior Fixation

The gold standard for surgical instrumentation in the treatment of neuromuscular scoliosis is Luque rod instrumentation with Galveston extension to the pelvis, cross-linkage (to prevent rod rotation and shift of the rods) with sublaminar wiring.¹² Surgical correction using both pedicle screw and hybrid fixation has also been successful in obtaining adequate correction.^{13,14} Other methods of pelvic fixation in neuromuscular scoliosis have been used to address associated pelvic obliquity.^{15,16} The unit rod incorporated these concepts into one unit and serves as a very powerful cantilever to correct scoliosis^{17,18} (especially lumbar and thoracolumbar curves) and pelvic obliquity. Technical difficulties with the unit rod include difficulty with pelvic limb placement (especially with hyperlordosis), problems

judging final rod length proximally, inadequate correction of severe rotational deformity, and having sufficient lever to correct upper thoracic scoliotic and kyphotic curves. More recently, the combination of pelvic screws, precontoured rods, properly placed cross-connectors plus sublaminar wire, and/or pedicle screws has allowed greater modularity and can minimize the technical difficulties of the unit rod.

AUTHORS' RECOMMENDED SURGICAL TREATMENT METHOD

Correcting Pelvic Obliquity

Fixation and fusion to the pelvis should be considered in every cerebral palsy patient to prevent late pelvic obliquity. Cantilever correction is a powerful method to correct pelvic obliquity^{7,19,20} (Dias 1996, Rinsky 1990, Tsirikos 2008). It requires instrumentation that can firmly anchor into the pelvis and can then be used as a lever arm to swing the pelvis into a corrected position that is perpendicular to the longitudinal axis of the spine. Traditionally, the unit rod (Fig. 103.6) is ideal for this purpose; however, it can be difficult to place the pelvic limbs of the rod in cases of severe pelvic obliquity and/or lumbar lordosis ($>70^\circ$), because it must be placed into the pelvis in one unit. Cantilever correction using pelvic screws connected to dual precontoured rods connected by a proximal connector (Figs. 103.7A and B) can also accomplish this. The pelvis is exposed by dissecting up over the sacroiliac joint

Fig. 103.6: The unit rod comes in variety of lengths for usage in neuromuscular scoliosis instrumentation.

**A**

Figs. 103.7A and B: The unit rod construct is pushed down manually at each level with the rod pusher prior to tightening the sublaminar wires, if used. If pedicle screws are used, it is still important at each level to push the rod down gradually to prevent plowing out of the screws. The spinous process must be kept centered between the rods.

**B**

onto the lumbar muscle attachment on the inner table of the pelvis. It is important not to dissect into the sacroiliac joint subperiosteally, as one can encounter significant bleeding here. By dissecting over the joint itself, little bleeding is encountered. The muscle is then sharply and bluntly dissected up over the iliac crest apophysis. The overlying fascia is then divided and the outer wing of the ilium is then subperiosteally exposed from the posterior superior iliac spine (PSIS) forward along the posterior one third of the pelvis and down to the sciatic notch. A guide that hooks into the sciatic notch is then utilized to aim a drill hole from the PSIS start point to just anterior and superior to the sciatic notch. If a guide is not available, the pedicle probe alone can be used and aimed just above the sciatic notch by direct palpation or by using intraoperative fluoroscopy. This is the region where the pelvis is most dense for pelvic rod or screw fixation.²¹ Intraoperative AP and oblique fluoroscopic views

(Figs. 103.8A to D) are taken to confirm the trajectory of the drill or probe to make sure that there is no penetration of the inner or outer pelvic table. Pelvic screw fixation of largest diameter possible (usually 7–10 mm diameter) is placed in this trajectory and should be of sufficient length to pass the sciatic notch by at least 1 cm. The authors prefer the use a closed polyaxial screw head to maximize the rigidity of the final rod-pelvic screw construct. Typically, we use pelvic screws alone; however, when additional fixation is needed to improve the rigidity of pelvic fixation, then we add S1 screws. We prefer this over sacral screw fixation alone, because pelvic screw fixation provides a better lever arm to correct both pelvic obliquity and sagittal plane pelvic deformity. Alternatively, pelvic screws can be placed using the medial portal as described by Sponseller.^{17,18} Advocates for this method state that there is less exposure time, less bleeding, and that the screw head is less prominent. While we have not found

Figs. 103.8A to D: Intraoperative fluoroscopy is used to obtain appropriate trajectory when drilling pelvic holes from the posterior superior iliac spine (PSIS) forward along posterior one-third of the pelvis to just anterior and superior to the sciatic notch. (A) Anteroposterior view shows the trajectory of the pedicle probe from the PSIS to just superior and adjacent to the sciatic notch. (B) Final screw position at least 1 cm lateral to the notch. (C) Oblique view shows the probe (arrow) and (D) final screw position between the inner and outer cortex just superior to the sciatic notch that appears as a “teardrop” (arrow).

bleeding or exposure time to be less in our hands, the screw is less prominent using this approach. We have obviated the screw head being prominent at the PSIS start point by notching the ilium at the entrance point with a rongeur and countersinking the screw. A fixed lateral rodded connector (usually 10 or 20 mm) is then used to connect each pelvic screw to a precontoured rod. Critical to the correction is to attach and secure each of the precontoured rods to the iliac screws with the fixed lateral connectors so that each of the rods is perfectly perpendicular to the horizontal axis of the pelvis and that the sagittal contour of the rods is aligned with the sacrum (Fig. 103.9). The sagittal bend should be identi-

cal on each rod and should also be aligned so that the contour matches from proximal to distal. If these steps are not meticulously done, the pelvic obliquity will not be fully corrected with the cantilever maneuver. Once this is done, the set screws on both the pelvic screws are tightened and torqued down onto the rod. A proximal connector is added at the top of the construct that strengthens the proximal construct. A drop entry cross-connector can be added in the lumbar spine to augment the stability of the construct.

Only if the patient has a leveled pelvis and adequate balance (“righting reflex”) should the surgeon consider ending fixation more proximal at L4 or L5. If fixation

to the pelvis is not done, fixation in the lumbar spine at a minimum of three levels with pedicle screw fixation is recommended. Cantilever correction and fixation to the remainder of the spine using screws or sublaminar wires can then be utilized.

Restore Trunk Balance

Trunk imbalance is most problematic in lumbar and thoracolumbar curves. Balancing the trunk is achieved with cantilever correction from distal to proximal. After the rod construct is “built” from distal to proximal as described above, cantilever correction can be started in order to correct pelvic obliquity and restore trunk balance. This begins by the surgeon pushing the rod down to the L5 lamina only

and then tightening the wire to the rod (a jet wire twister is helpful). Never use the wires to pull the rod to the spine. This is repeated in a step by step manner: push the rod down to the L4 lamina and then tighten down the wire, next the rod is pushed down to the L3 lamina and tighten the wire. The process is repeated one level at a time up to the T1 lamina (Figs. 103.10A to C). The wires are cut 1 cm in length and then bent and impacted down to the midline so as not to remain prominent. Just prior to tightening the wires at the proximal couple levels, the rod can be cut at the T1 level and the closed connector brought up to the proximal end of the rod and retightened and torqued, then final wire tightening. Alternatively, pedicle screws alone or a hybrid construct can also be used as segmental fixation points.

In cases where severe rotation is present (in the trunk or pelvis) and it is significantly impacting sitting or standing balance, pedicle screws should be used around the apex of the curve instead of sublaminar wires. Polyaxial reduction screws are recommended for the concave pedicles of the apical vertebrae in scoliosis or for both pedicles in hyperlordosis (see Fig. 103.11). Suggestions for poly versus uniplanar screws suggest reduction screws for hyperlordosis or all concave lumbar screws. Cantilever correction is then performed first, securing the rod to the spine with sublaminar wires or pedicle screws (depending on the level). A derotation maneuver at the level of the pedicle screws is then performed after the cantilever correction. It is important to have screws placed in at least 4–5 vertebral levels around the apex in order to distribute the derotational force and prevent plowing of the screws within bone that is often osteoporotic.

Fig. 103.9: The lateral connection to the iliac screws should make the rod perpendicular to the horizontal axis of the pelvis to maximize the cantilever correction.

Figs. 103.10A to C: The cantilever correction can be started after the rod construct is built from distal to proximal to correct pelvic obliquity and restore trunk balance. In step-by-step manner, the rod is pushed down to the lamina only and then the wire is tightened to the rod with a jet wire twister. Care must be taken to never pull the rod to the spine using the wires.

Fig. 103.11: Reduction of hyperlordosis can be achieved using pedicle screws with reduction posts.

Fig. 103.13: Due to insufficient lever arm, it is difficult to cantilever this type of thoracic curve to the unit rod.

Restore Sagittal Balance

Restoring sagittal balance is critical. Excessive kyphosis or lordosis may occur with or without the presence of scoliosis. Pedicle screws with reduction posts are placed in the region of the hyperlordosis (usually the lumbar spine).²² After securing them to the pelvis with pelvic screws (as described in the section on correcting pelvic obliquity), the precontoured rods are pushed down into the reduction post and secured with the set screw. Reduction of the

Fig. 103.12: Radiographs of a boy with hyperlordosis before and after surgical correction.

hyperlordosis is achieved by gradually screwing down the set screws (Fig. 103.11). Great care is taken to notice any evidence of posterior plowing of the screws. Dialing up the diameter of the screws may help with improved pedicle fixation. In addition, a sublaminar wire can be placed at the same level for additional fixation. Once the hyperlordosis is reduced, the remainder of the spinal instrumentation is completed, usually with sublaminar wire fixation (Fig. 103.12).

Hyperkyphosis can also be corrected using either a “distal to proximal” (in cases of lumbar or thoracolumbar kyphosis) or “proximal to distal” cantilever technique (in the case of a thoracic kyphosis). It is critical that fixation be completed up to at least T1 and occasionally C7 level to prevent “drop off” at the cervicothoracic junction. Firm fixation at the proximal-most end with two wires is recommended.

Centering the Head

The head being off center is most problematic in thoracic curvatures. Spinal curvatures in the thoracic region are more difficult to correct with cantilever correction. In such cases, starting distally at the pelvis or in the lumbar spine leaves a short lever arm at the proximal end of the rod by the time one reaches fixation in the thoracic spine. This makes it very difficult to center the head over the remainder of the thorax and pelvis. This type of curvature is very difficult to correct with the traditional unit rod since the unit rod requires distal fixation into the pelvis first (Fig. 103.13). With this type of curvature, fixation using the dual precontoured rods with proximal connector can be started

Figs. 103.14A to C: For thoracic scoliosis, proximal to distal cantilever technique can be used as demonstrated in the radiographs before and after surgical fixation.

proximally first. After exposing the spine and pelvis (in cases where pelvic fixation is required), pelvic screws and sublaminar wires are placed as previously described. The rod construct is then preassembled by first connecting the precontoured rods with the proximal closed rod connector at the top and placing a cross-connector in the lumbar region. The rods should be parallel from proximal to distal with respect to their contour. Next, the top of the rod construct is secured using sublaminar wires from T1 down to the apex of the curvature. After the apical vertebrae are secured to the rod, cantilever correction can be performed by gradually pushing the rod down to the next more distal vertebrae, tightening the sublaminar wire, pushing the rod down to the next more distal vertebrae and then tightening the wire, performing the same maneuver progressively down the spine until the pelvic screws are reached (Fig. 103.14). The fixed rodded lateral connectors are then utilized to connect the rod to the pelvic screws. Using this “proximal to distal” cantilever technique for cantilever correction allows for a better lever arm to correct thoracic scoliosis as well as thoracic kyphosis (Fig. 103.15), and to center the head over the trunk.

Maximize Fixation in Face of Osteoporotic Bone

As mentioned previously, quadriplegic cerebral palsy patients with severe osteoporosis require full evaluation of the bone density using DEXA scanning. In addition, evaluation of the vitamin D metabolism should be performed

by obtaining a full vitamin D panel, calcium, phosphorous, and alkaline phosphatase levels. Preoperative treatment may be necessary with several courses of IV pamidronate (in cases of osteoporosis) or with vitamin D (in cases of osteomalacia, usually secondary to seizure medication). Sublaminar wire fixation is preferred since the lamina has been shown to be biomechanically stronger than screws.²³ If screw fixation is necessary such as in cases of hyperlordosis or severe rotation, sublaminar wire fixation can be added at each level of screw fixation to add strength to the screw fixation points. In my own experience, this has been most commonly necessary at the L5 level. Alternatively, newer cortical fix pedicle screws may be used to help prevent this (Fig. 103.16). Also, dialing up the size of the pedicle with Clements pedicle dilators allows a bigger screw and better pedicle cortex fixation. Pedicle screw cement fixation can also be considered.

Minimizing Operative Time

Minimizing operative time is crucial, because the longer the spine is exposed, the higher is the risk of bleeding and infection. In general, passing sublaminar wires is faster than pedicle screw fixation and is more cost-effective in most surgeons’ hands who are well trained in both techniques. Most routine neuromuscular spinal deformity corrections can be performed with segmental sublaminar wire fixation alone. It is also more cost-effective than screw fixation. When pedicle screw fixation is performed, it is limited only to the levels that are needed, usually around

Figs. 103.15A to C: For thoracic kyphosis proximal to distal, cantilever technique can be used, shown in the radiographs before and after spinal fusion.

Fig. 103.16: Screw design of the cortical fix pedicle screw.

the apex of the scoliotic curve or in the region of hyperlordosis. In the case where epidural bleeding is problematic, pedicle screw fixation can also be considered to avoid more epidural bleeding. In our experience, however, epidural bleeding can be minimized by limiting removal of the ligamentum flavum to the central portion and avoiding going too lateral where the veins are more prominent. When epidural bleeding does occur, the application of surgifoam and thrombin usually stops it. Other consideration for minimizing the operative time includes careful preoperative assessment of curve stiffness. It is always best to consider scoliosis curve correction when the curve is under 70° and still flexible and therefore technically easier.

Sublaminar Wire Passage (Figs. 103.17A to G)

After the spine is completely exposed, the spinous processes are completely removed and the ligamentum flavum is carefully removed to expose the sublaminar spaces. Double Luque wires are bent (prebent wires are also available) and passed under the lamina of L5 up to and including the T1 lamina. The radius of curvature for the wire bend must approximate the width of the lamina to allow safe passage of the wire. Two double wires are passed at the L5 and the T1 lamina only while single wires are passed at each of the other levels. The wires are pulled up to equal length and then bent, with the midline bent flat down onto the lamina and the beaded end flat down onto the paraspinal muscles. This helps prevent the wires from getting inadvertently pushed into the spinal canal and allows for easier wire organization.

Anterior Release for Stiff Curves

It is safest to perform anterior release in a stiff curve to minimize the technical difficulty and risk of complication (loss of fixation) while attempting to correct a stiff deformity from a posterior approach alone. Posterior Osteotomies in combination with open anterior release. Some have advocated thoracoscopic anterior release. Anterior release may also be necessary in the case of severely stiff curves. The timing between anterior release and posterior instrumentation and fusion depends on the comorbidities of the patient. Alternatively, preoperative halofemoral traction has been reported to obviate the need for anterior surgery in stiff curves.²⁴

Figs. 103.17A to G: When passing Luque wires it is essential to roll the wires under the lamina (A to D) with extra caution taken not to catch the tip of the wire under the lamina, (E) placing the wire into the canal and ultimately place pressure on the spinal cord. (F and G) The wires are bent down the midline in the middle and the ends are bent flat down against the paraspinal muscles.

INTRAOPERATIVE AND POSTOPERATIVE CONSIDERATIONS AND COMPLICATIONS

Infection

The rate of infection after spinal deformity surgery in patients with neuromuscular disease contributes significantly to the morbidity of surgical intervention in this group of patients. Recently, a multicenter analysis of rates, risk factors, and pathogens following spinal instrumentation for scoliosis was done on 1,347 procedures performed in 946 patients. Procedures performed in patients with neuromuscular disease had the highest rate of infection at 9.2%.²⁵ Similarly, a retrospective review of 1,571 pediatric patients who had spinal deformity corrective surgery showed higher rates in patients with neuromuscular disease with the rates according to diagnosis being myelomeningocele 19.2%, cerebral palsy 11.2%, and myopathies 4.3%.²⁶ *Staphylococcus aureus*, *S. epidermidis*, and *Pseudomonas aeruginosa* were the most common organisms. Half of the patients required hardware removal to eradicate the infection and 41% of these patients had progression of their deformity. Others have cited enteric organisms such as *Escherichia coli*, *Enterococcus*, and *Proteus* as causative organisms later due to stool incontinence and concomitant urinary tract infection.^{27,28} Master and colleagues found that the presence of a ventriculoperitoneal (VP) shunt was a risk factor for infection.²⁹ At our own institution, we found that the two most significant associated factors with deep wound infection are the residual Cobb angle and the development of any postoperative wound breakdown. Other risk factors include malnutrition, allograft bone, increased blood transfusion, greater length of surgery, increased comorbidities, increased cognitive impairment, and urinary/stool incontinence.

Any measures taken to prevent postoperative infection are critical. Antibiotic prophylaxis should include coverage for *Staph aureus* and the surgeon should also consider coverage of methicillin-resistant *Staph aureus* (MRSA). Borkhuu and colleagues compared the risk of deep wound infection in a group of patients augmented by allograft mixed with gentamicin with a group augmented by allograft bone alone. The group with allograft mixed with gentamicin had an infection rate of 3.9% compared to 15.2% in the group with allograft bone alone. Currently, the senior author uses IV antibiotic prophylaxis with Ancef for patients with no comorbidities, and vancomycin or clindamycin in patients

with comorbidities, patients in chronic care facilities, and those colonized with MRSA. Liquid gentamicin (8–10 mg/kg body weight mixed with 30–60 cc of freeze dried allograft) is placed into the wound (Dias, 1996). A watertight closure of the wound is performed with a zero tolerance for any wound leakage. A surgical glue sealant system is used along with a moisture-protective bandage to prevent any stool or urine from contaminating the wound. If a wound infection does occur, an aggressive early irrigation is performed (multiple if necessary) with a vacuum-assisted closure of the wound and 6 weeks of IV antibiotics plus 6 months of suppressive per os or G-tube antibiotics are given as directed by the infectious disease specialists. Removal of hardware is done only in late or resistant infections (> 6 months).

Blood Loss

Jain and colleagues showed that cerebral palsy and other neuromuscular disorders had significantly higher normalized blood loss during spinal fusion than idiopathic scoliosis.³⁰ Brenn et al. stated that there is increased intraoperative blood loss that starts earlier in neuromuscular scoliosis compared to idiopathic scoliosis.³¹ While baseline prothrombin time and partial thromboplastin time were within normal range in neuromuscular scoliosis patients, they were still significantly different compared to that in idiopathic patients and by the time patients reached 15% blood loss, both were abnormal. The anesthesiologist and surgeon should be prepared for the possibility of major intraoperative blood loss. Increased bleeding was attributed to nutritional differences, altered tissue integrity, hepatic dysfunction, and the use of antiepileptic medications.

Type and cross-matched blood should be available up to twice the patient's blood volume as well as fresh frozen plasma and platelets. A cell saver machine is also helpful. In addition, core body temperature should be maintained at 37°C. Many patients are predisposed to hypothermia that increases bleeding. Antifibrinolytics may also have a role in reducing intraoperative bleeding.³²⁻³⁴

Currently, Amicar has been taken off the market leaving aprotinin and tranexamic acid for clinical use. Vitale and others have also shown some efficacy in the use of recombinant human erythropoietin in increasing hematocrit levels in children with neuromuscular disease undergoing scoliosis surgery.

Currently, our institution utilizes tranexamic acid in all patients with neuromuscular disease undergoing spinal deformity corrective surgery. Fresh frozen plasma and packed red blood cells are given early in the procedure.

Neurological Injury

Spinal cord monitoring should also be considered in patients who do standing transfers through ambulators.³⁵ The use of spinal cord monitoring is helpful in protecting lower extremity function when it is present. Using multiple recording sites of somatosensory spinal-evoked potentials and by administering motor-evoked potential procedures, it is possible to monitor spinal cord function in patients with neuromuscular disease, thus avoiding postoperative neurologic deficits.³⁶ While somatosensory cortical-evoked potentials are unreliable, somatosensory spinal-evoked potentials are possible to obtain in most cases used to detect sensory pathway integrity via testing the dorsal columns.³⁷ For those paralytic patients and myelomeningocele patients, it is not beneficial. Monitoring although possible during surgical correction of scoliosis due to cerebral palsy, it may be potentially unreliable.³⁸

Other neurological considerations include the postoperative evaluation of patients with pre-existing VP shunts to confirm the structural integrity of the shunt postoperatively compared to the preoperative evaluation (*see* Fig. 103.3). Symptoms of hydrocephalus may include headache, nausea, lethargy, cognitive changes, neurologic decline, or even death.

Cardiac

Cardiac arrest may occur from profound hypovolemia, hemo- or pneumothorax, air embolism, disseminated intravascular coagulation, or anaphylaxis due to latex. The surgeon should be especially mindful of hypotension during the corrective maneuver that can cause decreased venous return. We have also noted a decrease in intraoperative cortisol in many of the children with neuromuscular disease, especially those with upper motor neuron disease. In such case, cortisol is given intraoperatively to allow for an adequate stress response of the patient.

Respiratory

Postoperatively, frequent pulmonary toileting is necessary to prevent atelectasis and mucous plugging of major bronchi. Patients may be at risk for prolonged ventilator support postoperatively, especially if they have significant preoperative restrictive lung disease such as patients with muscular dystrophy and SMA.

Gastrointestinal

Postoperative ileus is common in patients with neuromuscular disease. Patients with G-tubes can begin feedings as soon as bowel sounds are heard. Gastrojejunostomy and nasojejunostomy tubes or hyperalimentation should be considered if regular feedings or oral intake is delayed much beyond 3–5 days. Pancreatic enzyme elevation and pancreatitis are common in patients with neuromuscular disease postoperatively.³⁹ Oral and gastrostomy feedings are avoided while pancreatic enzymes are elevated.

SPECIAL NEUROMUSCULAR DISEASE CONSIDERATIONS

Cerebral Palsy

The most prevalent neuromuscular disorder in most modernized cultures is cerebral palsy. It is a heterogeneous disorder that is caused by a static lesion to the immature motor cortex. The prevalence of scoliosis in the cerebral palsy population is proportional to the severity of neurologic impairment. It ranges from 5% in spastic diplegia to 64–74% in spastic quadriplegia. As scoliosis progresses, children who are dependent sitters with quadriplegic pattern involvement, initially demonstrate a postural scoliosis and kyphosis. In early and middle childhood, the spinal deformity is easily controlled with seating adjustments. In these early and middle stages of childhood, the structural element and flexibility of the scoliosis usually demonstrate little change. As the children enter into adolescence, however, particularly with the introduction of pubertal hormones and the adolescent growth spurt, the magnitude of the scoliosis increases dramatically, often at a rate of 2°–4° per month.^{1,2}

The magnitude of the scoliosis almost consistently increases to about 60°–90° range, which greatly affects sitting balance as well as head and arm control. Subsequently the stiffness of the structural curve follows thereafter roughly 6–12 months later. During this rapid increase in curve magnitude and stiffness, the family and caretakers commonly acknowledge the curve with increased problems in the child's head control, arm usage and upright sitting. The timeframe when the family and caretakers begin to notice and understand the problems caused by the scoliotic curve is approximately 2- to 3-years period whereby then the spinal deformity becomes fixed with minimal flexibility. Some children with severe quadriplegic pattern

involvement never develop scoliosis. For other individuals progression may be delayed into adulthood in patients with less neurologic deficit. In individuals who enter adulthood with mild scoliosis, the risk of continued progression is rather high. In one report, a curve $>40^\circ$ increased at a rate of 4° per year.⁴⁰ In adults with neuromuscular scoliotic curves over 40° , it has been recorded that progression continues to a mean of 80° .² Thometz and Simon, reported progression after skeletal maturity to be highest in lumbar and thoracolumbar curves $>40^\circ$. Other data suggest that curves as low as 20° at the end of growth may continue to advance at a rate of approximately 0.8° per year.¹

The scoliosis curve pattern in cerebral palsy can be classified by single versus double, and presence or absence of pelvic obliquity. Pelvic obliquity occurs secondary to the scoliotic deformity extending to the pelvis. Long C-shaped curves with pelvic obliquity generally occur in more severely involved nonambulatory patients with poor balance and righting reflex. Curves that are more S-shaped tend to occur in sitting or walking patients with better balance. Sagittal plane deformities are also a common problem, including lumbar hyperlordosis and thoracic hyperkyphosis. These deformities often cause discomfort and impair balanced sitting. Conservative treatment with seating modifications and bracing is temporary and does not halt progression of the spinal deformity. In younger children with flexible scoliosis, conservative management may allow the spine time to maximize growth while also temporarily assisting with upright sitting posture.

Surgical management for scoliosis is indicated in progressive curves over 60° when the child is not tolerating seating (in nonambulators) and standing (in ambulators). Surgery may also be indicated to alleviate pain or to correct pelvic obliquity prior to correcting a concomitant hip dislocation. Surgical correction of scoliosis and hyperkyphosis/hyperlordosis involves posterior spinal fusion with instrumentation usually from T1 or T2 down to the sacrum to prevent adding on above or below the fusion. Occasionally, fusion to the pelvis can be avoided in very good ambulators with excellent standing balance. These patients usually have more of an idiopathic curve pattern (double curve) indicating that they are able to “right” their head over the center of the sacrum through the development of a compensatory curve.

Myelomeningocele

This condition is a congenital malformation of the nervous system due to a neural tube defect of neuroectodermal

cells early in embryonic development leading to a varied spectrum of motor and sensory deficits. This congenital malformation has been associated with maternal hyperthermia and folate deficiency. Surgical repair of myelomeningocele may pose life-threatening complications with 24.4% of these children having associated scoliosis.⁴¹ Neurologic deterioration may occur at any age due to hydrocephaly, hydrosyringomyelia, Arnold–Chiari deformity, and tethered cord syndrome. Chronic skin ulceration and impaired pulmonary function often occur due to increasing spinal deformity. If scoliotic onset is sudden and associated with acute neurologic symptoms, one should suspect associated conditions of hydromyelia and tethered cord syndrome.

The level of spinal cord defect impacts the child’s clinical presentation, with generally the higher the level of defect, the greater the prevalence of spinal deformity. A long C-shaped curve is associated with a high level of paralysis and typically occurs at a young age. Those children in whom the last intact laminar arch was in the thoracic region developed scoliosis 89%, in upper lumbar levels 44%, and in lower lumbar levels 12%.⁴² Often the spinal curvature is a consequence of congenital deformity prompting hyperkyphosis and muscle imbalance distal to that segment malformation involving the trunk hip. Typically scoliotic curves $<40^\circ$ – 50° can be managed nonoperatively. Severe sagittal deformity, as well as hip contractures, can prevent sitting and comfortable positioning. Custom molded wheelchairs and sitting supports can offer temporizing upright positioning. Bracing younger children may also assist with comfort in sitting; however, bracing will not prevent eventual spinal deformity progression. Surgical intervention of significant hip contractures, which can worsen lumbar lordosis and scoliosis deformities, should be addressed before considering spinal surgery.

Surgical treatment can be uniquely challenging in this population due to the severe multiplanar spinal deformities, the presence of congenital vertebral malformations, absence of posterior elements, abnormal pedicle anatomy, truncal obesity, and compromised skin integrity. Preoperative considerations include the presence of shunts for hydrocephalus, Arnold–Chiari malformation, tethered cord, bladder augmentation procedures, bowel incontinence, thoracic insufficiency syndrome, and marked contractures of the lower extremity.

Preoperative CT scan and if possible intraoperative C-arm or O-arm navigation are helpful in the placement of pedicle screw that is often necessary due to the frequent

Figs. 103.18A and B: (A and B) Pedicle screw placement into the lower lumbar vertebral bodies and sacral promontory can be better obtained after completing osteotomies of the iliac wings.

absence of the posterior elements. Careful planning of skin incisions away from pre-existing scarring should be performed. The medial portal, S2 iliac pelvic screw placement is especially helpful in these patients as it avoids screw prominence. The combination of truncal obesity, combined with increased lumbar lordosis may make it difficult to cannulate pedicles that are very laterally positioned. Osteotomy of the iliac wings is helpful to allow better pedicle cannulation and trajectory of the pedicle screw placement (Figs. 103.18A and B). Postoperative wound management is important. Skin closure can be challenging and the assistance of the plastic surgeon to close the skin can be extremely helpful in case there is a need to mobilize skin and/or muscle flaps to gain closure. Low pressure mattresses should also be considered postoperatively (Figs. 103.19A to F).

Spinal Muscular Atrophy

This disorder is an autosomal recessive disease with two genes on the chromosome 5q locus of the survival motor neuron gene and neuronal apoptosis inhibitory gene. The result is diminished abundance of the protein resulting in death of neuronal cells in the anterior horn of the spinal cord and subsequent system-wide muscle atrophy.⁴³ There is a slow progression of weakness without sensory impairment caused by disease of motor neurons in the spinal cord and brainstem. Patients tend to deteriorate over

time; however, prognosis varies with SMA type and a great degree of individual variability. Recurrent respiratory problems are the primary cause of morbidity.

Four forms of the disease exist: type 1 infantile (Werdnig-Hoffmann, onset age 0–6 months), type 2 intermediate (Dubowitz, 6–8 months), type 3 juvenile (Kugelberg-Welander, >18 months), and type 4 adulthood (sometimes a subset of type 2).⁴⁴ Most children with early disease die at a young age and thereby have no spinal treatment. Those children with intermediate and juvenile types who grow into adolescence develop progressive spinal deformity, with most often the curve beginning in the first decade. Scoliosis tends to progress 8° per year, and when children become nonambulatory the curve progression occurs at 3° per year.⁴⁵ The most common curves are thoracolumbar and single thoracic patterns, with a third of patients having an associated kyphosis deformity. Even though these curves are of large magnitude, they often are flexible. Prevention of curve progression is not affected by bracing; however, in younger patients may allow further spine growth until surgical fusion is necessary.⁴⁶

Posterior stabilization should extend from T3 to the sacropelvis. In some patients, the pelvis can be rather small, with abnormal anatomy and poor bone quality leading to challenging pelvic fixation. In patients with excessive lordosis distal rod fixation as well can be difficult. Pelvic fixation into the iliac crest or S2 screw insertion can be useful in these situations. In the early postoperative

Figs. 103.19A to F: Preoperative and postoperative radiographs and clinical pictures of a nonambulatory patient with mid-lumbar level myelomeningocele progressive kyphoscoliosis.

period, the major complications are related to atelectasis, pneumonia, and respiratory function. Decline in percentage predicted force vital capacity in patients with SMA type 2 and 3 was 7.7% per year preoperatively and reduced to 3.8% after spinal corrective surgery.⁴⁷ Due to progressive neuromuscular weakness of the disease, pulmonary function continues to regress. After spinal stabilization even though pulmonary function declines, a straight spine positioned over a level pelvis provides upright sitting, better upper extremity function, and improved quality of life and caretaking.

Muscular Dystrophy

This condition is a group of muscle diseases that weaken the musculoskeletal system characterized by progressive

skeletal muscle weakness, defects in muscle proteins, and the death of muscle cells and tissue.⁴⁸ Predominantly these conditions are inherited; however, mutations of the dystrophin gene and nutritional defects at the prenatal stage are also possible. Dystrophin protein is found in the muscle fiber membrane and often there is a loss of muscle mass that may be difficult to appreciate as some types of muscular dystrophy cause a pseudohypertrophy due to fat and connective tissue build up. These muscle diseases include Becker's muscular dystrophy, congenital muscular dystrophy, Duchenne muscular dystrophy, facioscapulo-humeral muscular dystrophy, distal muscular dystrophy, Emery-Dreifuss muscular dystrophy, limb-girdle muscular dystrophy, myotonic muscular dystrophy, and oculopharyngeal muscular dystrophy.

Duchenne muscular dystrophy is a sex-linked recessive condition involving a defect on the Xp21.2 locus on the X chromosome leading to a marked decrease or absence of the protein dystrophin.⁴⁹ Death usually occurs in the second or third decade resulting from pulmonary or cardiac failure. Children become progressively weaker as they advance in age and eventually become nonambulatory. Scoliosis affects 90–100% of patients who do not ambulate.^{50,51} One study suggests that in nonambulatory children scoliosis was absent in 10% and mild or $>30^\circ$ in 13%.⁵⁰ Modalities of bracing, lordotic positioning, and wheelchair modification may delay but will not prevent spinal deformity. Steroid therapy has been shown to slow progression of weakness, allow longer ambulation, and reduce the progressive scoliosis.

Curve progression correlates strongly with a decline in respiratory function, and early surgery has the advantage of preserving cardiopulmonary function. Even though patients with Duchenne muscular dystrophy have progressive, restrictive lung disease, the lung function is related to curve magnitude. In general, surgical intervention should be undertaken once the curve reaches 35° before critical respiratory decline occurs. Peak progression of scoliosis occurs between 13 and 15 years of age at 1° – 3° per month. Posterior spinal fusion for scoliosis is associated with a significant decrease in the rate of respiratory decline.⁵²

Typically fusion includes high-thoracic level of T2 or T3 to L5 or S1 and has similar results in the apex of the curve that is above L1, and if the scoliosis is $<40^\circ$ with pelvic obliquity $<10^\circ$, then fusion to L5 is sufficient. If apex of the deformity is below L1, fusion should extend to the pelvis.⁵³ Operative fixation has been shown to be successful with posterior-only pedicle screw fixation achieving balanced sitting posture and maintenance of deformity correction.^{54,55} Instrumentation with Luque system Galveston pelvic fixation and sublaminar wires, two rods with cross-links, or a unit rod have proven stable. Other options included using segmental fixation with all pedicle screws or combination of wire and pedicle screw fixation. Postoperatively the major complications are related to blood loss and pulmonary problems. All fixation options fulfill the crucial goals to permit immediate immobilization postoperatively, maintain upright sitting balance, and maximize comfortable function.

Spinal Cord Paralysis

Spinal cord injury is an insult to the spinal cord resulting in a change, either temporary or permanent, in the cord's

normal motor, sensory, or autonomic function. Depending on where the spinal cord and nerve roots are damaged, the symptoms can vary widely, from pain to paralysis. Regarding the mechanism of injury, there appeared to be two distinct mechanisms that affected younger children and adolescents. Motor vehicle accidents typically affect younger children, whereas adolescents are frequently injured during sporting activities.⁵⁶

One study examined children who sustained spinal cord injuries between birth and age 21 years to review the rate of scoliosis progression. Patients who sustained injury before the adolescent growth spurt had 97% development of spinal deformity, whereas those after adolescent growth had 52%.⁵⁷ Because of these differences, traumatic spinal cord injury should be highly suspected in the presence of abnormal neurological examination, a high-risk mechanism of injury, or a distracting injury, even in the absence of abnormalities on plain radiographs. The predominant curvature type is that of a long C-shaped curve. Bracing may be effective in small curves $<20^\circ$; however, it is neither demonstrated where bracing is effective at preventing curve progressing in those deformities $>20^\circ$ nor delay the time to corrective surgery.⁵⁸

The preoperative considerations that are specific to children with spinal cord injury include assessment for the presence of potential urinary tract infections, evaluation for deep venous thrombosis (DVT) with ultrasound of all four extremities,⁵⁹ and ensuring a bowel “clean out” the day before surgery. Most of these patients require long fusions from T1 to T2 down to the pelvis. Of special note, however is that these patients rely on an increased kyphosis to perform activities of daily living such as self-catheterization. The anesthesiologist should avoid giving succinylcholine that may cause sudden cardiac arrest.⁶⁰ When performing surgery, the surgeon must keep this in mind and should consider observing patient for a period of time in a temporary TLSO to preoperatively plan the optimum sagittal profile to fuse the patient in. The lateral profile of the rods can be prebent to match the lateral radiographs. Usually the final sagittal profile of the fusion provides for some kyphosis. Postoperatively, prophylaxis for DVT should be considered.

Rett Syndrome

Rett syndrome is an X-linked disorder. Some children have a mutation on the MECP2 gene. It affects females almost exclusively. Childhood development is normal until 6–18

months of age at which time a rapid deterioration in cognitive and motor function occurs. The majority of these children have a seizure disorder. The neurological picture may become relatively static for many years after the initial deterioration. Clinically, the spectrum of motor involvement is variable with some children remaining ambulatory and others becoming wheelchair-bound. Rett syndrome is often mistaken for cerebral palsy. Scoliosis is reported in up to 80% of patients. Long C-shaped curves are common. Younger children presenting with scoliosis have a higher progression rate. Bracing is usually ineffective in preventing curve progression. Surgical fixation is similar to that of the cerebral palsy patient with screw fixation to the pelvis and sublaminar fixation up to T1 or T2. Surgical treatment in Rett syndrome after spinal fusion provides successful correction and restoration of sitting balance. Larsson and colleagues prospectively followed 23 consecutive girls after spinal fusion and assessed sitting balance, number of seating supports, weight distribution, time used for rest, and Cobb angle, all improved after surgery.⁶¹

OUTCOMES

In general, the goals of spinal surgery in patients with neuromuscular disorders are to enhance quality of life by improving balanced sitting and posture, improving pulmonary and gastrointestinal function, and reducing pain and deformity. However, neuromuscular surgery is rather challenging. In a large multicenter study reviewing cases of pediatric scoliosis, neuromuscular scoliosis had 17.9% complications.⁶² In our series of 107 patients, complications included 14 deep infections, 3 deaths, 15 cases of prominent hardware, and 1 pseudarthrosis.¹⁰ The primary instrumentation for treatment of neuromuscular scoliosis is the unit rod instrumentation. It is simple to use, considerably less expensive than most systems, associated with low complication and reoperation rates, and achieves successful long-term correction 70–80% of the preoperative curvature magnitude and 80–90% correction of pelvic obliquity.^{7,20} In ambulatory patients with cerebral palsy who had posterior spinal fusion using unit rod instrumentation all of 24 patients maintained ambulatory status postoperatively.⁶³ Sagittal plan deformity has also been effectively corrected using the unit rod in patients with hyperlordosis and kyphosis.⁴

Neuromuscular scoliosis is associated with increased hospital stay and risk of complications. Nonambulatory status preoperatively and curve magnitude of $\geq 60^\circ$ were

directly associated with increased risk of major complications and indirectly associated with increased length of hospital stay.²⁹ Progressive pulmonary disease typically seen in patients with neuromuscular disease often is related postoperatively to development of pulmonary complications. Those patients with neuromuscular disease with a preoperative force vital capacity of $<39.5\%$ of predicted value, forced expired volume of $<40\%$, cob angle $>69^\circ$, or age >16.5 years were found to have increased likelihood to have postoperative pulmonary complication.⁶⁴

Important aspects of postoperative assessment include overall function, appearance, ease of care, and improved quality of life. Outcome measures should differentiate treatment effects from underlying disease functional impairments.⁶⁵ Some might question whether spinal deformity corrective surgery is truly beneficial for patients with neuromuscular disease, particularly those most severely involved. In one survey of 190 parents and caretakers assessed for functional improvement in children with cerebral palsy after spinal fusion, 95.8% of parents and 84.3% of caretakers would recommend spinal surgery again.⁶⁶ Multiple reviews report caretakers, families, and patients with severely involved neuromuscular diseases are most often satisfied with the surgical correction, improved appearance, and enriched quality of life.⁶⁷⁻⁷⁰

INTRODUCTION

Goals of Treatment

Adolescent idiopathic scoliosis (AIS) is a three-dimensional deformity of the spine, affecting 1–3% of children in the at-risk population of children between the ages of 10 and 16 years.¹ The prevalence of AIS diminishes as curve size increases; the prevalence of curves above 20° is 0.3–0.5% and for curves over 30° this drops to 0.2–0.3%.² While AIS can progress rapidly during growth, this disease process rarely has effects that are so dramatic that immediate surgery is necessary. Nonetheless, scoliosis that develops during adolescence can affect patients during their youth and throughout later stages in life. In fact, the effects of AIS can manifest much later in life after the spinal curvature surpasses a critical threshold, and beyond this point there is increased risk of further progression and health problems such as pain, torso deformity, psychological disturbance, and pulmonary dysfunction.³

While advocates of early surgery emphasize the benefits of surgical deformity correction with regard to physical and psychological outcome, opponents base their arguments on the risk of complications and the fact that despite encouraging results with short and intermediate follow-up, the subjective long-term outcomes are yet to be fully elucidated.⁴ The goal of nonoperative treatment is to decrease the need for surgical intervention by

reversing, arresting, or slowing the curve progression thereby preventing undesirable outcomes in adulthood. Nonoperative treatments for AIS include observation, bracing, physical therapy, and other novel therapeutics.

Assessment of the AIS Patient

When assessing patients with AIS, it is important to identify those patients who are at greatest risk of progression to a larger curve. Larger Cobb angles and skeletal immaturity have long been identified as key clinical predictors of curve progression.⁵ A thorough history will reveal other potential risk factors for progression, including a family history of scoliosis. On physical examination, appearance and overall balance of the patient should be assessed. Tanner staging can help indicate the developmental maturity of the child (Figs. 104.1A to H). A paraspinal prominence may be detected on Adams forward bending test and may be further evaluated with a scoliometer, which is a tool used to measure the degree of spinal deformity while bending forward. A detailed neurological examination should be performed to provide a baseline assessment and to look for possible deficits. Radiographs are necessary in order to assess the coronal and sagittal degree of the curve, as well as the curve pattern and rate of curve progression over time. The Risser Sign, a quantification of iliac apophysis ossification, has long been an important indicator of skeletal maturity and is associated with risk of curve progression

Figs. 104.1A to H: Tanner staging: (A) **Stage 1:** The key finding in stage 1 is that all of the digital epiphyses are not covered. In this case, the patient is at the end of stage 1. Particularly noticeable at the third middle phalanx, the epiphysis is not as wide as the metaphysis. More often, this finding is most noticeable on the fifth middle phalanx and metacarpal head. (B) **Stage 2:** The key finding in stage 2 is that all of the digital epiphyses are covered. In this case, the patient is near the end of stage 2. The epiphyses are now all as wide as their metaphyses (covered). The dorsal and palmar surfaces of the metacarpal heads are clearly delineated. There is some capping of the second through fifth proximal phalanges but nowhere else. (C) **Stage 3:** The key finding in stage 3 is that the preponderance of the epiphyses cap their metaphyses. The capping is a small bend over the metaphyseal edge. In the metacarpals, the second through fifth heads are wider than the metaphyses. The epiphyses cap the thumb metacarpal and all of the digits. (D) **Stage 4:** The key feature of stage 4 is the beginning of distal phalangeal physal closure. In this case, the distal phalangeal physis of the thumb appears closed on the radiograph, but its rotation makes it more difficult to see than the other digits. The distal phalangeal physes of the second through fifth digits are beginning to close. Physal closure starts in the center of the physis. The remainder of the digits are fully capped, and the metacarpal heads are wider than their metaphyses as in stage 3. (E) **Stage 5:** The key feature of stage 5 is that all of the distal phalangeal physes are closed. If there is any black (growth cartilage) rather than white (physal scar) in the physis, the radiograph remains as stage 4. The remainder of the epiphyses are capped, and the metacarpal heads are wider than the metaphyses (see stage 3 as demonstrated in Table 104.1). (F) **Stage 6:** The key feature of stage 6 is that some of the proximal or middle phalangeal physes are closing. In this stage, all of the distal phalangeal physes are closed and some of the proximal and middle phalangeal physes are closing. The second through fifth metacarpal physes typically stay open longer than those of the other small bones. When the metacarpal physes go from black (physis) to white (physal scar), then the physis is considered "closed" or "fused" for this staging system. (G) **Stage 7:** The key feature of stage 7 is that all of the physes, except for those of the distal parts of the radius and ulna, are closed. There are no black physal lines remaining for any digits or metacarpals. Stage 7 ends when the distal radial and ulnar physes are white (physal scar) rather than black (persistent physis). (H) **Stage 8:** The key finding of stage 8 is closure of all physes. The residual physal lines may appear white, but there are no black physal lines. *Source:* Available from <http://health-7.com/Atlas%20of%20Pediatric%20Physical%20Diagnosis/Tanner%20Staging/1>.

(Fig. 104.2).⁵ More recently, the Sanders-described Simplified Tanner-Whitehouse Scale (“Sanders stage,” for short), using hand radiographs, has proven to be another useful prognostic indicator of progression.⁶ Sanders staging allows for the assessment of skeletal maturity based on ossification of the digital epiphyses, phalangeal physes, and radial physis. The greatest utility of Sanders staging is its ability to quantify maturity within Risser stage 0—the level of maturity most associated with risk of progression.

The correlation of the Sanders stage with the curve acceleration phase was 0.91 (Table 104.1). While it is not routine, pulmonary function testing may also be used as a tool in patients who exhibit or complain of pulmonary symptoms. The literature has demonstrated that pulmonary function may be negatively impacted in patients with AIS, although the clinical implication of this impact in patients with nonsurgical curves has not been fully elucidated.^{7,8}

Table 104.1: The simplified Tanner-Whitehouse-III system vs. other maturity assessments.

Stage	Key features	Tanner-Whitehouse-III stage	Greulich and Pyle reference	Related maturity signs
1. Juvenile slow	Digital epiphyses are not covered	Some digits are at stage E or less	Female 8 yr + 10 mo, male 12 yr + 6 mo (note fifth middle phalanx)	Tanner stage 1
2. Preadolescent slow	All digital epiphyses are covered	All digits are at stage F	Female 10 yr, male 13 yr	Tanner stage 2, starting growth spurt
3. Adolescent rapid—early	The preponderance of digits are capped. The second through fifth metacarpal epiphyses are wider than their metaphyses.	All digits are at stage G	Female 11 and 12 yr, male 13 yr + 6 mo and 14 yr	Peak height velocity, Risser stage 0, open pelvic triradiate cartilage
4. Adolescent rapid—late	Any of distal phalangeal physes are clearly beginning to close (see detailed description in the text)	Any distal phalanges are at stage H.	Female 13 yr (digits 2, 3, and 4), male 15 yr (digits 4 and 5)	Girls typically in Tanner stage 3, Risser stage 0, open triradiate cartilage
5. Adolescent steady—early	All distal phalangeal physes are closed. Others are open.	All distal phalanges and thumb metacarpal are at stage I. Others remain at stage G.	Female 13 yr + 6 mo, male 15 yr + 6 mo	Risser stage 0, triradiate cartilage closed, menarche only occasionally starts earlier than this
6. Adolescent steady—late	Middle or proximal phalangeal physes are closing	Middle or proximal phalanges are at stages H and I	Female 14 yr, male 16 yr (late)	Risser sign positive (stage 1 more)
7. Early mature	Only distal radial physis is open. Metacarpal physeal scars may be present	All digits are at stage I. The distal radial physis is at stage G or H	Female 15 yr, male 17 yr	Risser stage 4
8. Mature	Distal radial physis is completely closed	All digits are at stage I	Female 17 yr, male 19 yr	Risser stage 5

Scoliscore, a prognostic genetic test that became available in 2009, uses a saliva sample to test 52 genetic markers associated with curve progression (Table 104.1). There is an algorithm based on this assay and the size of the curve at the time of diagnosis that creates a score between 1 and 200. This score indicates risk of curve progression to $>40^\circ$. While this test has been validated by its manufacturer, its clinical utility is dubious.^{9,10} Some propose that the test may be most useful in further stratifying patients with high-clinical risk of progression (i.e. Risser 0–1 and Cobb angle $>20^\circ$) in order to reduce unnecessary bracing and radiographic testing¹⁰ (Table 104.2).

ARGUMENT FOR OBSERVATION

The nonoperative treatment of AIS consists of observation, bracing, physical therapy, and other novel therapies. A central issue of debate pertaining to these treatments is whether bracing actually achieves what it purports to do, i.e. halts curve progression by unloading biomechanical stress on the spine. Between 1970 and 2012 the topic remained moot due to a general dearth of quality evidence to support bracing versus observation. Studies with

wide methodological variability, various biases, and, in many cases, a lack of control subjects all contributed to a clouded picture of the efficacy of bracing.¹¹ This has led many to advocate for “watchful waiting,” and has spurred debate regarding the effectiveness of regular screening for scoliosis in schools. In 2004, the US Preventative Services Task Force recommended against routine screening for asymptomatic AIS. However, a joint position statement from the American Academy of Orthopaedic Surgeons (AAOS), Scoliosis Research Society (SRS), Pediatric Orthopaedic Society of North America (POSNA), and American Academy of Pediatrics (AAP), citing a lack of evidence in the current literature, did not recommend against scoliosis screening and stated that if screening were to take place it should be performed twice for females at ages 10 and 12 years, and once for males at age 13–14 years.¹² Others have advocated strongly for observation noting that late-onset idiopathic curves rarely lead to organ failure, compromised future health, or social stigma; and in some cases, the decision to operate might be for purely cosmetic reasons.^{13,14} One retrospective review of 153 patients treated at a single institution with a policy of recommending against bracing for AIS found that, when the rate of surgical correction is used as the primary outcome, there was no advantage to bracing over observation.¹⁵

A second issue for consideration in the discussion of bracing versus observation is the potential risk to the child. Apart from pressure sores and discomfort, no major physical risks for bracing have been reported, though there is some literature examining the effect of bracing on mental and social health. In the practice of prescribing scoliosis braces it is common to encounter patients who's self image, psychosocial health, and quality of life (QOL) appear to suffer. However, several studies examining the effect of bracing on QOL have been conducted with the predominance of the evidence supporting the notion that bracing does not have a significant negative impact on self-image or QOL in AIS.^{16–19} Moreover, at long-term follow-up, AIS patients who were braced or observed reported QOL scores that did not differ from the population norms.²⁰

The multicenter prospective cohort study by Nachemson and Peterson, widely cited^{13,15,23} and considered to be some of the highest quality evidence to investigate bracing versus observation, studied 240 female subjects with AIS assigned to bracing, observation, or electrical stimulation. This study found that 36% of braced patients versus 66% of observed patients failed treatment (defined as $>6^\circ$ of progression).²¹ However, a 2007 literature review

by Dolan and Weinstein that pooled data from 18 studies regarding the need for eventual surgical intervention found no clear difference between braced or observed patients, though it did acknowledge several potential confounders including the heterogeneity of inclusion criteria used in studies, vague surgical indications, and the limited number of observed patients (only 139 observed subjects from three studies were included).²² The calls for a trial similar in scope and design to Nachemson and Peterson's original 1996 prospective study have not gone unheard—the results of Bracing in Adolescent Idiopathic Scoliosis Trial (BrAIST), a randomized, multicenter trial comparing observation to 18 hours of daily brace wearing, were published in the *New England Journal of medicine* in 2013. An analysis including both the randomized and preference cohorts (patients who chose bracing over observation), showed a rate of treatment success of 72% after bracing, as compared with 48% after observation. BrAIST concluded that bracing “significantly decreased the progression of high-risk curves to the threshold for surgery in patients with adolescent idiopathic scoliosis” and that “the benefit increased with longer hours of brace wear.”²⁴ Despite the strong conclusions in BrAIST, bracing treatment should be prescribed judiciously, taking into account Society on Scoliosis Orthopaedic and Rehabilitation Treatment (SOSORT) and SRS bracing criteria, access to the appropriate clinical resources, and, of course, the patient's overall clinical picture. Further consideration of bracing options and indications will be discussed later in the chapter.

■ BRACING

A Brief History of Bracing

The long and varied history of nonoperative attempts to correct spinal deformity begins in the 5th century BC with Hippocrates' attempts to apply axial distraction with an extension apparatus—the scamnum. Galen proposed adding direct pressure to the spine through use of binders and jackets in combination with Hippocrates' traction, and was a proponent of exercises thought to strengthen the chest wall musculature in an attempt to achieve distraction indirectly.^{25,26} A series of French efforts, beginning in the early 16th century with Paré's advocacy for iron corsets to be applied at 3-month intervals during the post-pubescent growth spurt was followed by Nicholas Andre's mid-eighteenth century theory that the development of scoliosis was purely postural and could be remedied through use of bracing or corsets and proper chair construction—a precocious attempt at ergonomic design.²⁶

Jean-Andre Venel, a Swiss orthopedist, used traction beds and bracing techniques at his hospital dedicated to the treatment of childhood skeletal deformities. A century later in the 1880s, Lewis Sayre applied plaster of Paris casts to patients' torsos—the “Sayre jacket”—while holding them in overhead traction, was merely an adjunct to the “gymnastic exercises” that he felt were necessary to strengthen the musculature at the convexity of the curve and inevitably improve sagittal balance.^{27,28} 1924 saw the advent of Lovett and Brewster's “turnbuckle” cast consisting of two sections of plaster cast hinged at the concavity with a screw that served to apply distraction to the convexity of the curve. It was recommended for full-time use, though the device was cumbersome, excessively restrictive, and merely applied a bending force without traction in light of the observation that bending a curve—as opposed to pulling on it, or applying traction—is a much more effective means of straightening it.²⁸ This theory, though slightly modified as a result of a more developed understanding of biomechanics, would surface again in the development of nocturnal bracing in the late 20th century.

Medical management and understanding of scoliosis remained fairly rudimentary until Roentgen's Nobel prize-winning introduction of the X-ray to medical science in 1895.³³ Rapid advancements in the technology over the next several decades led to relatively high-quality spinal films by the 1930s, and, for the first time, an appreciation of the three-dimensional nature of the scoliotic deformity. At the same time that the X-ray was developing, the increased incidence of tuberculosis and poliomyelitis led to a spike in spinal deformity, and the new surgical techniques developed by Hibbs, Risser, and Ferguson to treat the sequelae of Pott's disease and Polio were later applied to patients with idiopathic scoliosis.²⁶ Still, Risser's method, in which preoperative traction and casting held surgical candidates immobilized for up to a year prior to surgery and 8–10 months afterward in the “Risser immobilizer” (a modified turnbuckle cast that utilized an external frame to apply traction to the curve while also addressing the rotational deformity), gave a nod to the use of bracing in correction of spinal deformity.²⁸ Ponseti and Friedman's retrospective report of 117 fusions at 3-year follow-up noted that of the 100 cases attempting adjunctive correction with a “Risser jacket,” 81 achieved a preoperative correction of at least 20°. This work, which also attempted to classify outcomes based on the severity of the curve, its location, and its etiology, set the stage for the development of treatment guidelines for both surgical and nonoperative treatment of

scoliosis.²⁹ With the development of both devices and bracing techniques spurred on by their use in the surgical treatment of scoliosis, bracing for scoliosis as the primary intervention became an attractive and viable option.

Brace Types

Milwaukee Brace

First developed in 1946 by Blount and Schmidt for the postoperative adjunctive treatment of scoliosis secondary to poliomyelitis, the use of the Milwaukee brace for the nonoperative treatment of scoliosis gained popularity after the 1958 publication of their experiences with the brace in chronic and postoperative poliomyelitis and as a means of preventing the rapid progression of the curve at the end of the growth period.³⁰ Termed a cervicothoracolumbosacral orthosis, the Milwaukee brace applies traction to the spinal deformity through use of a steel and leather pelvic base from which one anterior and two posterior arms extend to support the head at the occiput and throat (Fig. 104.3). Derotational forces are applied at rib prominences through pads attached to the pelvic girdle or support arms. This class of brace has historically been used for higher thoracic and cervicothoracic curves, because thoracolumbosacral orthoses (TLSO), such as the Boston brace, fail to apply corrective forces to curves with an apex higher than T7–T8.

Wilmington Brace

Developed in 1969 at the request of a patient who refused both the Milwaukee and Risser braces, the Wilmington

Fig. 104.3: Milwaukee brace.

brace is the first significant and successful low-profile TLSO.²⁸ Its construction involves creation of a plaster cast of the patient's torso while applying traction and hand pressure to achieve the desired correction to the longitudinal and transverse deformities. The plaster cast is then used to fashion a model of the patient's torso on which the full-contact plastic jacket is modeled. Radiographs taken prior to removal of the initial plaster cast as well as after the brace has been fitted to the patient ensure that the desired curve correction and balance are achieved.³¹

Boston Brace (Figs. 104.4A and B)

The Boston brace is a TLSO similar to the Wilmington brace in both theory and design; however, the Boston avoids the

Figs. 104.4A and B: Boston brace for (A) thoracic curves (B) thoracolumbar curves.

difficulties associated with the molding process necessary for creation of the Wilmington brace by utilizing a modular system consisting of prefabricated components of varying sizes. The three basic brace types (lumbar, thoracolumbar, and thoracic) are designed for correction of curves with apices at spinal levels as high as T7, while various extensions (e.g. a modification to correct hypokyphosis) and additional padding allow for custom modification of the individual modules and application of corrective forces where necessary. In addition to applying forces that passively correct the curve (i.e. pads located at the curve apex or just below it), the standard model applies mild lumbar flexion and areas of relief opposite each area of force to promote curve correction as the patient actively pulls away from pressure zones. The brace also addresses rotational deformity through application of coupled rotational forces in the same rotational direction.

The Boston brace has gained popularity as an alternative to the Wilmington brace due to its low profile, ease of application, and high patient satisfaction and compliance. Proponents of the Boston bracing system advocate for a team model wherein the surgeon, orthotist, and physical therapist apply their specific expertise and knowledge in combination to fabricate a brace and treatment plan that provides for the greatest chance of successful treatment.³²

The Rigo Chêneau Style Brace (Fig. 104.5)

The Rigo Chêneau style brace was developed in Spain by Dr. Manuel Rigo in the early 1990s and, as the name suggests, represents an adaptation of the earlier Chêneau theory of bracing. The Rigo Chêneau brace has a highly contoured, multiplanar design that acts through three-point curve correction, derotation and counter-rotation of the curve, and sagittal correction. Brace shape is determined through application of a scoliosis classification system which includes both radiographic and clinical criteria. In addition, the brace provides open space over the curve concavity that allows rib cage expansion during breathing. This active force assists in the repositioning of trunk muscles and remodeling of the rib cage as it expands into the volumes allowed by the contours of the brace.

The role of physical therapy in treatment with the Rigo Chêneau brace deserves special mention as the brace's emphasis on active correction through guided breathing facilitates synergy between the corrective action of the brace and the corrective action of scoliosis specific exercises.²²

Fig. 104.5: The Rigo Chêneau style brace.

Night-time Bracing

The benefits of night-time bracing include improved patient compliance as night-time wear circumvents the psychosocial and self-image issues that accompany brace-wearing. The thought is that for a select group of patients with significant compliance issues, some brace wearing is better than none. Additionally, night-time brace wear allows patients to remain physically active during the course, which some have hypothesized may promote spontaneous correction.^{34,35}

Charleston Bending Brace (Fig. 104.6)

Hooper's Charleston bending brace was developed in 1978 primarily to address compliance issues in patients with AIS in whom other treatment options had failed.

Fig. 104.6: Charleston bending brace.

The Charleston brace operates on the principles that dominated original bracing techniques such as Lovett and Brewster's turnbuckle brace, i.e. passive bending of the spine without traction can promote correction of spinal deformity by inducing stretching forces on the concavity of the curve and compression at the convexity. This technique is applied most effectively in patients with single lumbar or thoracolumbar curves between 25° and 40°,^{33,34} and in these cases effectiveness has been shown to be comparable to the Boston brace.³⁵ A study of the Charleston bending brace's biomechanics has confirmed that the major effect of the brace on the scoliotic curve consists of unloading the tensile and compressive forces as was hypothesized by the brace's designers. However, there is some concern that this method of bracing can negatively affect compensatory curves.³⁶

Providence Brace (Fig. 104.7)

Similar to the Charleston brace, the Providence brace is designed for night-time use only, as it severely limits mobility; however, the Providence brace applies lateral and rotational forces to bring the deformity toward the midline rather than simply bending the spine. Creation of the Providence brace involves placing the patient in the supine position and creating a plaster cast of the torso while applying the desired derotational and apical forces through use of lumbar and stabilizing pads. Similar to the Charleston brace, this plaster cast becomes a positive mold of the corrected torso from which a polypropylene brace incorporating the standard pressure and void regions is formed. The resulting orthosis has been shown to be effective in addressing rotation, as well as double curves and some thoracic curves under 35°, though correction of higher thoracic curves is typically less successful.³⁷ Special care should be taken to avoid excessive pressure that may result in patient discomfort, pressure sores, and noncompliance.

Fig. 104.7: Providence brace.

Soft Braces: The SpineCor Brace

The SpineCor brace represents a departure from the traditional rigid bracing options and operates on the theory that addressing the factors that confound effective bracing—namely, noncompliance due to the appearance of and discomfort created by rigid bracing—will lead to better outcomes. The SpineCor bracing method uses a flexible plastic pelvic base as the anchor for elastic bands that connect to a cloth vest and apply corrective force while promoting normal posture. Force and directionality of the elastic bands are determined through three-dimensional computerized reconstruction of the patient's posture using software provided by the manufacturers.³⁸

The application of the brace is similar to that of existing TLSOs, where the patient is instructed to use the brace a minimum of 20 hours per day. As this is a relatively new corrective device, a limited body of evidence exists to support its use, though a prospective study from 2008 showed that progression of the curve during treatment was significantly higher in subjects using the SpineCor brace compared to those using more traditional, rigid bracing systems (Table 104.3).³⁹

Table 104.3: Application and indication for brace types.

Brace	Application	Indication
Boston lumbar brace	Daytime TLSO	Apex below L1; 20°–45° curve
Boston thoracolumbar brace		Apex from L1–T10; 20°–45° curve
Boston thoracic brace		Apex from T10–T7; 20°–45° curve
Rigo Chêneau style brace	Daytime TLSO	Apex from T-6 to below L-1; 20°–45° curve
Charleston brace	Nocturnal bending brace	Single thoracolumbar and lumbar curves from 25°–40°; Risser sign of 0–2
Providence brace	Nocturnal brace	Thoracolumbar and lumbar curves <35°

Bracing Practice

Indications

The goal of bracing in the AIS population is to halt the progression of scoliosis. Therefore, the indications for bracing are in large part guided by the risk of curve progression and skeletal maturity of the child. For example, in Sponseller's review of bracing for AIS,⁴⁰ it is suggested that curves of 25°–45° in children with Risser Signs of 0–1—indicating the potential for rapid growth—should be offered a brace on initial evaluation. A number of clinical and radiographic indicators exist to gauge the potential for curve progression and the skeletal maturity of the child.

The specific role of genetics in the natural history of AIS is an area of growing interest for researchers. A large body of evidence supporting a hereditary component of scoliosis makes a positive family history of progressive scoliosis particularly concerning for progression in the child.^{41–43} Gender and maturity are also implicated in accelerated progression.¹⁰ Females are reported to have a higher incidence of AIS as well as a higher risk of progression than males.^{44,45} Additionally, markers of physiologic immaturity also raise concern for progression. These include younger age, premenarchal status, and lower Tanner staging. Radiographic imaging can also suggest progression, as Risser signs of 0–1 suggest that significant skeletal growth remains. More recently, Sanders's Simplified Tanner-Whitehouse-III staging classification has been used in this population, with a score of 4 or lower indicating an increased risk for curve progression.^{6,46}

The relative contraindications to bracing are related to the nature of the curve and the medical and emotional health of the patient. Children with high thoracic curves may be difficult to brace as the shoulder girdle is poorly tolerated and lordotic thoracic spines have also proved difficult to brace.⁴⁰ The risk of progression decreases as patients near skeletally maturity, and initiation of bracing in late-adolescence is unlikely to change the course of the child's scoliosis. Overweight children have been reported to experience higher rates of failure with bracing, which is likely due to the interference of excess body mass on the brace's transmitted corrective forces.⁴⁷ Medical conditions that may limit or prevent the use of a brace include respiratory and digestive problems. Furthermore, behavioral and mental health issues such as attention deficit hyperactivity disorder, anxiety, autism, and psychosis can lead to noncompliance or even physical harm to the child.

Bracing Protocol, Follow-up, and Cessation

Once the decision to brace has been made, the time in-brace and follow-up intervals must be determined by the provider. Following collaboration by the orthotist and provider to create the brace, Sponseller suggests an in-brace radiograph with a minimum 30% correction of thoracic curves and 50% correction of thoracolumbar and lumbar curves to be adequate.⁴⁰ If in-brace correction fails to reach 15–20%, the appropriateness of the brace for the child should be reevaluated. Our department's practice is to time the first in-brace radiograph at 4–6 weeks following the initiation of bracing. This allows for patients to become accustomed to the brace and brings issues pertaining to comfort and feasibility to the attention of the provider.

The recommendation for time spent daily in-brace ranges from 12 to 23 hours, depending on the source. Katz et al. reported that progression of scoliosis while treated with a Boston brace was inversely related to the number of hours spent in-brace, and patients who utilized the brace for >12 hours per day experienced the best outcomes. BrAIST reported a treatment success rate of >90% among patients who wore their braces 12.9–17.6 hours per day.¹⁶ However, patient compliance must be considered on an individual basis when making brace-time recommendations.⁴⁸ For example, if a patient is highly compliant, a prescription to use the brace for 20 hours/day, may be a reasonable recommendation. On the other hand, if a relatively noncompliant patient could only handle 14 hours/day in-brace, prescribing more time may be a discouraging obstacle. Overall, data does suggest that control of progression of AIS is more likely when a patient is in-brace for a minimum of 12 hours/day.⁴⁸ If a patient is unable to meet in-brace time requirements, then the appropriateness of bracing should be reevaluated.

After the initial in-brace radiograph and recommendations for use are provided, a follow-up interval of 4–6 months is appropriate. Brace comfort and any reports of skin breakdown should be investigated as these can lead to noncompliance and dermatologic issues. Based upon the fit of the brace and growth of the patient, it may be appropriate to create a new brace at the discretion of the orthotist or provider. Patients should be directed to abstain from bracing for 24 hours prior to follow-up appointments where out-of-brace radiographs will be obtained as curve progression can be masked by radiographs taken in the brace. In addition, bone age X-rays for Sanders score,

pelvic films to evaluate the triradiate cartilages, and Risser sign should also be taken to assess the patient's skeletal maturity.

Cessation of bracing should be considered if the child is skeletally mature or if there is failure to control progression of the curve. Signs of skeletal maturity include a growth history of <1 cm within a 6-month interval, female patients beyond 1-year postmenarche, and radiographic findings such as a Risser sign of 4–5, Sanders 7–8, or closed distal radial physis.⁴⁰ If follow-up radiographs reveal significant curve progression despite bracing, then cessation of bracing should be considered.

PHYSICAL THERAPY

Physical therapy is a somewhat controversial nonoperative treatment option for AIS. Scoliosis-specific exercises (SSE) are taught to patients by therapists who are especially trained in these methods and they aim to reduce the deformity caused by scoliosis. While this modality is commonly used in Europe, it remains controversial in the United States and is used variably in clinical practice.

History

Exercise-based treatment for scoliosis dates back to Hippocrates and has been used for centuries in Europe.⁴⁹ The modern era of treatment for scoliosis with physical therapy began in Germany in the 1920s with the development of a program by Katharina Schroth. The initial Schroth therapy program focused on inpatient postural correction, proprioception, and breathing techniques, and was followed by daily home exercises. While the foundation

of Schroth therapy is essentially unchanged today, certain aspects of the treatment have evolved over time, including an adaptation of the therapy for outpatient settings.⁴⁹ The most recent development in Schroth-based therapy is the concept of integrated scoliosis rehabilitation (ISR), which incorporates therapy into activities of daily living. Other scoliosis-specific programs with similar principles to the Schroth method have been developed in recent years, including Dobomed, Side-shift, and SEAS (Scientific Exercises Approach for Scoliosis).⁵⁰

Indications

There are no evidence-based indications for the use of physical therapy in AIS patients; however, experts in scoliosis-specific physical therapy published consensus indications in 2006 that vary based on the patient's Cobb angle and level of skeletal maturity. Patients who are ideal for treatment with outpatient physical therapy alone are those patients who have small curves (15°–25°) and significant remaining growth (i.e. Risser 0; Sanders <4). Physical therapy is recommended in combination with brace treatment when skeletally immature patients reach a Cobb angle of 25° and have a high risk for curve progression.⁵¹ One relative indication to consider in any patient who may be a candidate for scoliosis-specific physical therapy is whether or not they are motivated to participate in a time-intensive therapy program and perform daily exercises on their own. Therefore, patients and family members who chose to undergo this therapy must be adequately counseled about the requirements of this treatment (Fig. 104.8).

Fig. 104.8: Schroth patient.

Methods of Treatment

Autocorrection is one of the primary principles of SSE, and is defined as the ability of a patient to improve their deformity through active postural realignment of the spine in three dimensions.⁵⁰ Schroth-based programs are designed specifically for each patient based on their individual curve pattern, and they focus on improving scoliotic posture, postural proprioception, and breathing patterns through “elongation, realignment of trunk segments, arm positioning, and corrective muscle tension.”⁶⁰ Dobomed, Side-shift, and SEAS therapies are based on similar principles but use slightly different approaches to achieve curve correction. It is important to note that SSE are different from general physical therapy, which often includes low-impact stretching and strengthening exercises, which the literature has shown to be ineffective for treating scoliosis.⁵⁰

The initial Schroth program was designed to include 4–6 weeks of inpatient therapy, followed by home exercises for 30 minutes per day after the initial treatment period. Many treatment studies have used this model, although the program has also been adapted for outpatient use. The period of outpatient therapy may be modified to fit the needs of each patient, with as little as 3–4 months of therapy for 2 hours per day and twice per week, although these individual modifications to the program have been less clearly studied. Following the initial intensive period of therapy, patients are instructed to perform daily home exercises.⁴⁹

Evidence for the Use of Physical Therapy

Several studies argue that scoliosis-specific physical therapy programs, both inpatient and outpatient, have the ability to decrease curve magnitude and progression.^{52–56} The goals of physical therapy are to decrease bracing requirements, prevent the need for surgery, improve physical appearance (i.e. rib hump), improve pulmonary function, and/or to decrease the psychological burden of the curve deformity.⁵⁷ A 2011 systematic review identified 20 studies that investigate the utility of physical therapy in AIS treatment, and the authors concluded that exercises can be effective in reducing the curve progression rate and/or improving Cobb angles, as well as reducing brace prescription. It should be noted that the evidence quality of the studies in this review is low—only one randomized-controlled trial is included, and the majority are

retrospective and many lack controls.⁵⁰ A Cochrane review published in 2012 cites two studies (154 patients) with low-quality evidence for the benefit of physical therapy in AIS, and it found that “better quality research needs to be conducted before the use of SSE (SSE) can be recommended in clinical practice.”⁵⁸ These papers highlight the need for more rigorous research to be performed in order to determine whether physical therapy programs are truly beneficial to AIS patients.

In addition to curve correction, an improvement in vital capacity has been demonstrated in two studies; however, it is unclear whether this effect is clinically significant.^{59,60} Curve correction through physical therapy may also decrease the rate of chronic back pain that has been demonstrated in adult patients with a history of AIS.⁸ The potential psychological and general health benefits of an exercise-based treatment program should not be overlooked; patients who participate in this type of therapy may benefit from improvements in overall body image and self-confidence through the completion of daily exercises. This type of treatment requires the patient to actively participate in their own treatment program, and therefore improvements in appearance and function further empower and motivate patients to participate in their own care (see Fig. 104.7).

Difficulties with Physical Therapy Treatment

A major criticism of physical therapy as a treatment for AIS is that there is weak evidence to support its use and long-term benefits, leaving many physicians skeptical of its true utility. Nearly all of the data demonstrating the success of this therapy comes from a few centers in Europe, and it is unclear if these results are replicable in other patient populations throughout the world. It is also unclear if the beneficial effects of this therapy are maintained once therapy is discontinued. Furthermore, because physical therapists must be trained in SSE programs, access to adequately trained therapists will be an issue for many patients. Frequent long distance travel may not be feasible for many patients, and there may be additional financial burdens for family members as a result of their child's therapy sessions.

While the use of physical therapy as a treatment for AIS remains controversial in the United States, there is potential for research growth in this area. A positive prospective trial would improve the support for its use, but as it stands,

this therapy remains an unproven, resource-intense treatment modality with limited evidence for effectiveness. Regardless, it still may serve as a low-risk treatment option for highly-motivated patients who wish to avoid bracing and surgery.

OTHER TREATMENT MODALITIES

There exist other treatment modalities in AIS beside observation, bracing, and physical therapy. However, these treatments are neither well studied nor supported by evidence. Chiropractic or osteopathic manipulation, acupuncture, exercise, and nutritional therapies have all been asserted as possible treatments or adjuncts to treat AIS, and all have little to no support for their use.⁶¹ Finally, electrical stimulation of spinal musculature has been explored to treat progressive AIS, but this has shown to be less effective than bracing.⁶²⁻⁶⁴

CONCLUSION

Nonoperative management of AIS is generally reserved for those patients who are at risk of progression due to skeletal immaturity. The most commonly employed treatment methods are observation, bracing, and physical therapy. If the risk of progression is deemed high by the provider as evidenced on history, physical examination and radiographic findings, then halting the progression of the curve becomes a therapeutic priority. The BrAIST trial has provided strong evidence that bracing of curves between 25° and 45° is more effective than observation at preventing progression to surgery when compliance is ideal. Physical therapy has been shown to be at least temporarily efficacious in select patients as well, but the demands of these methods are often prohibitive for children and their families. Therefore, it is important for providers to understand the select populations of patients that may benefit from these nonoperative therapies. Furthermore, it is important to take the appropriate measures to understand the patient from a holistic perspective in order to determine the optimal treatment course for the child and their family.

KEY REFERENCES

Dolan LA, Weinstein SL. Surgical rates after observation and bracing for adolescent idiopathic scoliosis. *Spine.* 2007;32(19S):S91-100.

This study is a systematic literature review that included 18 studies pertaining to bracing versus observation with the endpoint of surgery for the indication of AIS. They found that bracing and observation showed no clear advantage with similar rates of surgery in each group, although no recommendation could be made due to the low levels of evidence the studies exhibited.

Nachemson A, Peterson L. Effectiveness of treatment with a brace in girls who have adolescent idiopathic scoliosis. A prospective, controlled study based on data from the Brace Study of the Scoliosis Research Society. *J Bone Joint Surg.* 1995;77:815-22.

This prospective, center-randomized, international study with 286 girls showed that bracing with a Boston TLSO was successful in 74% of patients compared to 34% in the observation cohort. Follow up was 4 years following initiation of brace and this is high-level evidence toward the efficacy of bracing.

Sponseller PD. Bracing for adolescent idiopathic scoliosis in practice today. *J Pediatr Orthop.* 2011;31(1 Suppl):S53-60. This review article is a synthesis of the evidence pertaining to bracing as well as a protocol description of bracing practice.

SURGICAL INDICATIONS

The goals of operative intervention in AIS are to prevent progression of the curve, correct the three-dimensional deformity, and obtain a balanced spine. Curve magnitudes $>50^\circ$ at the time of skeletal maturity have a propensity to progress throughout adulthood despite cessation of growth.¹ Progression of deformity in untreated AIS has been associated with back pain, cosmetic concerns, restrictive pulmonary disease in large curves, and a negative self-perception of health.²⁻⁷ Therefore, a spine curvature $>45^\circ$ in immature patients and 50° in mature patients is indicated for spinal fusion.

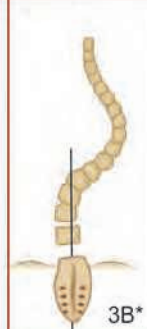

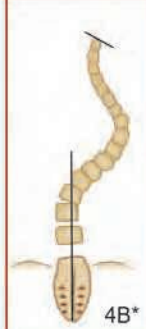

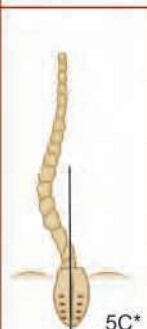

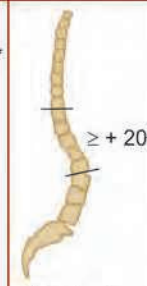

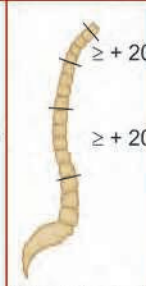

PREOPERATIVE PLANNING

Surgical intervention in AIS presently involves placement of instrumentation to anchor rods to the spine, correction of the deformity via mechanical methods, and fusion of the instrumented segments to maintain the corrected spinal alignment. The methods for achieving correction and fusion include anterior and posterior spinal approaches. The major decision-making during preoperative planning involves selection of the approach, identifying the major and minor curves that require instrumentation, and select the appropriate spine segments to instrument to correct and balance the spine—all while preserving the maximum number of motion segments in the spine.

Classification

The King classification first described patterns of deformity to allow prediction of fusion levels in AIS with major thoracic curves. Based on their review of 405 patients with AIS, they created a uniplanar classification system guiding distal fusion levels to adequately balance the coronal plane deformity.⁸ The primary focus was to ensure that the distal fusion level was centered over the sacrum, and specifically for King type II curves, a selective thoracic fusion could be performed to achieve that result.⁸ Limitations of this classification system included absence of the sagittal and axial planes and fair to poor intra- and interobserver reliability, necessitating a more comprehensive classification system.⁹⁻¹²

In 2001, Lenke et al. published a new classification system that described the deformity in both the coronal and the sagittal plane (Fig. 105.1).¹³ They identified three components that helped guide the extent of spinal fusion in AIS—curve type (1–6), lumbar (L) spine modifier (A, B, C), and a sagittal thoracic modifier (–, N, +), and proved that it was reproducible among a group of seven independent spine surgeons from the Scoliosis Research Society (SRS) (Fig. 105.1).¹⁴ The L spine modifier refers to the relationship between the apex of the L curve and the center sacral vertical line (CSVL): A—CSVL is between the pedicles, B—CSVL touches the apical vertebral body, C—CSVL

Lumbar spine modifier	Curve type (1–6)					
	Type 1 (main thoracic)	Type 2 (double thoracic)	Type 3 (double major)	Type 4 (triple major)	Type 5 (TL/L)	Type 6 (TL/L-MT)
A (No to minimal curve)	 1A*	 2A*	 3A*	 4A*		
B (Moderate curve)	 1B*	 2B*	 3B*	 4B*		
C (Large curve)	 1C*	 2C*	 3C*	 4C*	 5C*	 6C*
Possible sagittal structural criteria (to determine specific curve type)	 Normal	 PT kyphosis	 TL kyphosis	 PT + TL kyphosis		

*T5–T12 sagittal alignment modifier: -, N, or +
 - is $<10^\circ$ N (normal) is $10\text{--}40^\circ$ + is $>40^\circ$

Fig. 105.1: The Lenke classification—type 1, thoracic; type 2, double thoracic; type 3, double major (thoracic $>$ lumbar); type 4, triple major; type 5, thoracolumbar/lumbar; type 6, double major (lumbar $>$ thoracic). Lumbar modifier A—center sacral vertical line (CSVL) is between pedicles on apical lumbar vertebra, B—CSVL touches apical lumbar vertebra, C—CSVL is medial to apical lumbar vertebra. Thoracic modifier (-)— $<10^\circ$ T5–T12 kyphosis, (N)— $10^\circ\text{--}40^\circ$ T5–T12 kyphosis, (+)— $>40^\circ$ T5–T12 kyphosis.

is medial to the apical vertebral body. The sagittal thoracic modifier refers to the amount of kyphosis measured between T5 and T12: (-) <10°, (N) 10°–40°, (+) >40°. Numerous studies have affirmed the validity of the Lenke classification in determining fusion levels, identifying curve patterns amenable to selective fusion, and preventing postoperative decompensation.^{15–18}

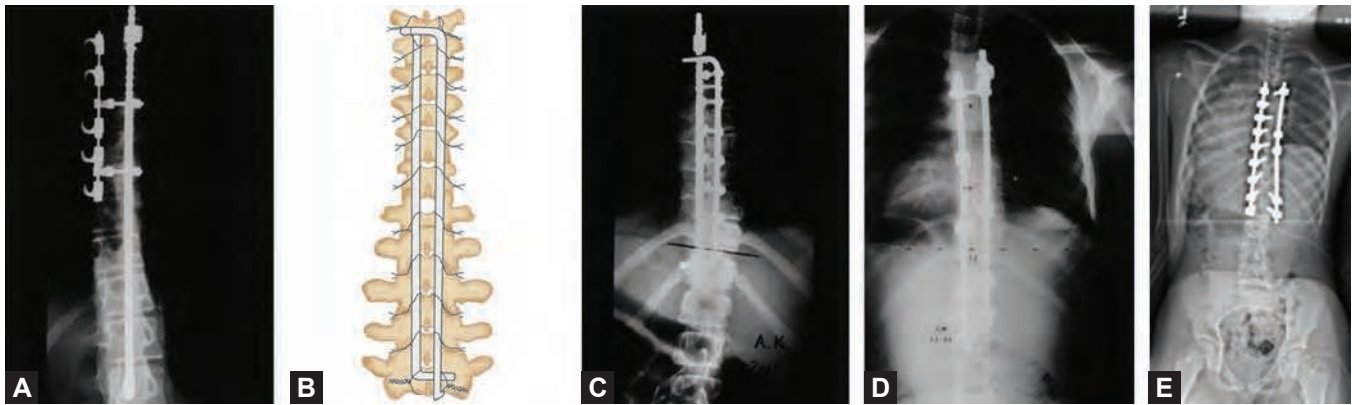

Suk et al. has created a classification system that aims to better characterize the three-dimensional deformity, guide fusion levels, and direct treatment of the deformity in all planes.¹⁹ Consisting of four curve types: thoracic—single and double, and L—single and double, the distal fusion level is determined based on two types of curves, A and B. For thoracic curves, the A and B characterization depends on the relationship between the end vertebra (EV) and neutral vertebra (NV): A—distal NV is within one of the EV; B—the distal NV is located two to three levels caudal to the EV. For L curves, the A and B characterization depends on the position of L3 on bending films—its relation to the CSVL and the Nash-Moe rotation. Distal direct vertebral rotation (DVR), as a means to derotate the uninstrumented portion of the spine and improve correction while limiting the extent of fusion, is a standard concept in addition to apical DVR. Other concepts intrinsic to

Suk's classification include pedicle screw instrumentation, a rigid rod for derotation and complete pedicle fill on the concave side of the spine. The selection of thoracic/lumbar and A/B guides the direction of the distal DVR and the lowest-instrumented vertebra (LIV) (Tables 105.1 and 105.2).¹⁹

The Lenke classification is most commonly utilized for describing curve patterns and drives preoperative decision-making regarding the extent of spinal arthrodesis. However, it does not capture the three-dimensional character of the scoliotic deformity. The SRS is currently developing a new three-dimensional classification system.^{20,21}

Flexibility

Assessing the flexibility of the spine preoperatively is helpful primarily for assessing the structural nature of the minor curves and determining the proximal and distal extent of the fusion, and secondarily, for providing insight into the amount of correction attainable during surgery. King,⁸ Lenke,¹³ and Suk¹⁹ all use supine side-bending films to determine the structural nature of curves and guide the extent of fusion. Traction films demonstrate more curve flexibility when assessing curves >50° compared to side-bending and

Figs. 105.2A to E: Evolution of spinal instrumentation. (A) Harrington instrumentation, (B) Luque instrumentation, (C) Wisconsin segmental spinal instrumentation, (D) Cotrel-Dubousset instrumentation, (E) pedicle screw instrumentation.

push-prone radiographs.²²⁻²⁵ However, selecting distal fusion levels based on traction films results in a higher incidence of “adding on” and should be avoided.²⁵ Push-prone films are helpful to assess the response of the uninstrumented spine to correction of the primary curve, especially in selective thoracic fusion.^{26,27} Radiographs assessing the flexibility of the spine should be used to assist in determining the extent of fusion, but ultimately levels should be chosen according to the standing posteroanterior and lateral radiographs.

Magnetic Resonance Imaging

The value of a preoperative magnetic resonance imaging (MRI) lies in identifying any underlying spinal pathology that is causing the scoliosis and should be addressed prior to deformity correction surgery. Indications for MRI include an abnormal neurologic examination including asymmetric abdominal reflexes,²⁸ left thoracic curve, and absence of thoracic apical lordosis.²⁹⁻³³ Patients with presumed AIS and a normal physical and neurologic examination do not require a preoperative MRI.³⁴

Intraoperative Neuromonitoring

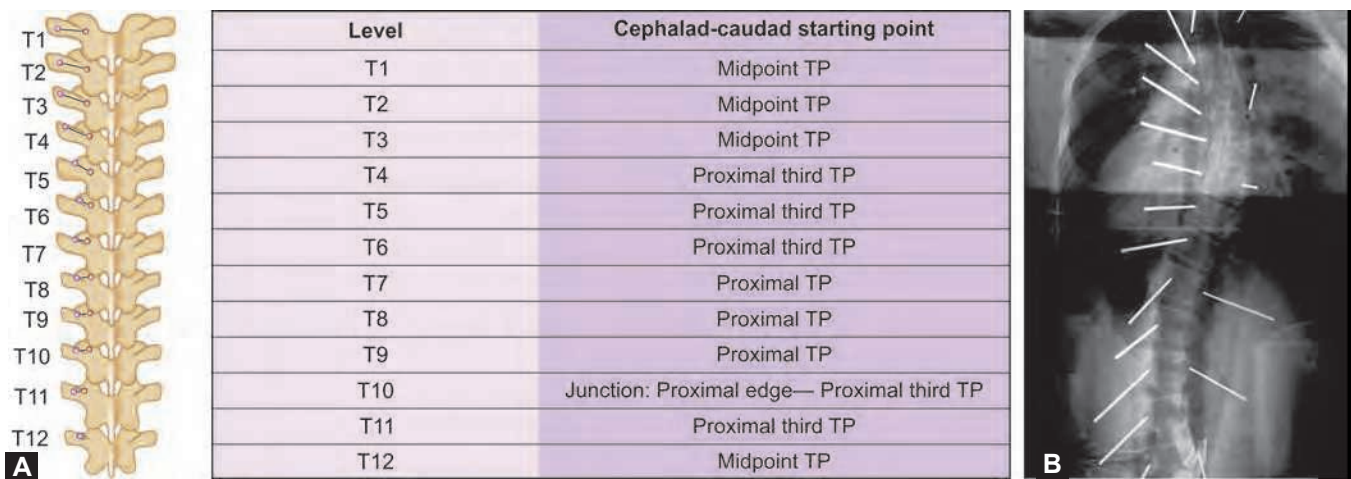

The most devastating complication from scoliosis surgery is neurologic injury; therefore, it is paramount to utilize intraoperative neuromonitoring. The Stagnara wake-up test was first employed to assess gross motor function during surgery.³⁵ Possessing significant limitations including premature extubation, patient recall, prolonged surgical time, and the potential for false positives and negatives, the Stagnara wake-up test was replaced by intraoperative spinal cord monitoring beginning in

the late 1970s.³⁶⁻³⁸ Somatosensory-evoked potentials were the first neuromonitoring technique instituted and continue to be a part of current monitoring strategies while TcMEPs have become the standard of care for monitoring motor pathways.³⁹⁻⁴² Somatosensory-evoked potentials and TcMEPs are adequately sensitive and specific to warrant a prompt response by the surgeon when a critical change in monitoring occurs to avoid the potential for a neurologic deficit.^{39,41}

OPERATIVE TECHNIQUE

Surgical treatment of AIS includes an anterior, posterior, or combined approach with instrumentation and fusion. Traditionally, an anterior approach is beneficial for preventing the “crankshaft phenomenon”⁴³ when substantial growth remains in an immature patient, i.e. open triradiate cartilages. The anterior approach also offers an advantage over the posterior approach, as fusion levels can typically be limited to EV to EV. The posterior approach allows for exposure of the spine to the width of the transverse processes, meticulous facetectomies and preparation of the bony surface to allow for fusion, and placing instrumentation with hooks and/or pedicle screws to achieve arthrodesis.

The evolution of spine instrumentation is closely associated with the deformity correction techniques that corresponded with that implant system. Distraction-based Harrington rod instrumentation (Fig. 105.2A)⁴⁴ was followed by Luque double L-rod segmental instrumentation that used wires to draw the spine to the rods (Fig. 105.2B). The Wisconsin segmental spinal instrumentation system was a

Figs. 105.3A and B: Pedicle screw placement. (A) Freehand technique—anatomical location of thoracic pedicles to properly identify and place pedicle screws in the thoracic spine. (B) Suk et al. technique of placing a Kirschner-wire in each pedicle to be instrumented and obtaining a single radiograph to ensure proper placement.⁵⁷

hybrid of Harrington and Luque techniques and avoided intracanal instrumentation (Fig. 105.2C).^{45,46} Cotrel and Dubousset introduced the concept of derotating the spine with a concave rod-rotation maneuver (Fig. 105.2D).⁴⁷ This technique was employed initially utilizing hooks as the anchor points to the spine, and subsequently has been replaced by pedicle screws in a hybrid (Fig. 105.2E) or all-pedicle screw construct. Much debate exists involving the superiority of hybrid versus all-pedicle screw constructs with the weight of the literature favoring all-pedicle screw constructs for improved pulmonary function,^{48,49} greater coronal correction,^{49,50} better maintenance of coronal and sagittal correction,⁵⁰ less LIV tilt,⁴⁹ fewer revisions,⁵¹ greater improvement in main thoracic (MT) scolimeter measurements,⁴⁹ fewer spine segments instrumented,⁵² and higher patient satisfaction.^{49,50,53} Hybrid instrumentation outperforms pedicle screw constructs in restoring kyphosis,^{52,54} avoiding proximal junctional kyphosis,⁵⁵ surgery time,⁵⁰ and blood loss.⁵⁰

Safe placement of pedicle screws is paramount to successfully performing PSF. Numerous techniques have been described to place thoracic pedicle screws safely including freehand (Fig. 105.3A),⁵⁶ plain radiograph or fluoroscopic-guided (Fig. 105.3B),⁵⁷ and computed tomography-navigated techniques.^{58,59}

Selective Thoracic Fusion

A mindset for preserving spinal motion should influence the identification of curves to include in the fusion

mass. Performing a selective thoracic fusion indicates instrumenting the major thoracic curve in the presence of a minor thoracolumbar (TL)/L curve that crosses the midline and will be left untreated. The benefit of preserving the lumbar motion segments must be balanced by the ability to achieve spinal balance with a selective thoracic fusion and to correctly identify lumbar curves that will not progress. The Lenke lumbar modifier (B or C)¹³ helps identify these curves, in addition to objective radiographic parameters of the major and minor curves relative to each other—Cobb angle [MT/compensatory lumbar (CL) >1.2, apical vertebral rotation measured by Nash-Moe⁶⁰ (MT/CL >1.0), and apical vertebral translation ratios (MT/CL >1.2).^{61–63} The clinical appearance, e.g. rib and lumbar prominences and trunk balance, provides insight into the structural nature of a curve and whether the patient will tolerate the residual deformity. Lastly, the distal extent of a selective thoracic fusion must correlate with the sagittal profile to avoid junctional kyphosis.

Selective thoracic fusion, when levels are properly selected, has good surgical outcomes.⁶⁴ The uninstrumented L curve will correct an average of 19–66%^{61,65,66} and SRS-24 results will be good provided coronal balance has been restored.⁶¹ Pedicle screw instrumentation results in greater thoracic and spontaneous L correction compared to hybrid constructs.^{66,67} Risk factors for “adding-on” or coronal decompensation include an LIV that is two levels proximal to the NV⁶⁶ or an LIV that is proximal to the stable vertebra⁶⁵ (Fig. 105.4).

Fig. 105.4: Selective thoracic fusion. Properly balanced selective thoracic fusion with the stable vertebra being selected as the lowest instrumented vertebra.

TL/L Curves

Major structural curves of the TL or L spine are possible candidates for selective fusion as well. A nonstructural thoracic curve $<50^\circ$ with a bend to $\leq 20^\circ$, TL/L: thoracic Cobb ratio ≥ 1.25 , and closed triradiate cartilages can be considered for selective TL/L fusion from an anterior approach.⁶⁸ Traditionally, this approach involves the spine segments from EV to EV and is able to gain excellent correction while saving fusion levels compared to a posterior approach.⁶⁹ Shufflebarger et al. demonstrated that a posterior approach with an all pedicle screw construct from EV to EV was effective at correcting the deformity.⁷⁰ A comparative study between two practices demonstrated significantly better curve correction, less loss of correction at minimum 2-year follow-up, and shorter hospital stays for posterior, all-pedicle screw constructs compared to anterior instrumented fusions.⁷¹ Therefore, TL/L curves can be instrumented from an anterior or posterior approach with positive results (Fig. 105.5).

Double and Triple Major Curves

Combined thoracic and L structural curves require PSF with instrumentation. Proximal and distal fusion levels must include all structural curves to prevent decompensation.^{72,73} The LIV should be touched by the CSVL, the caudal disc should not open to the convexity, and the LIV should not have significant rotation.

Direct Vertebral Rotation

Direct vertebral rotation is a mechanism for correcting the axial plane spine and chest wall deformity associated with scoliosis. As first described by Lee et al. in 2004, thoracic scoliosis is first corrected by a precontoured rod placed into the concave, segmental pedicle screws and a derotation maneuver is performed.⁷⁴ Then, DVR is performed by rotating the screws in the juxta-apical vertebrae, on the concave and convex sides, opposite to the direction of the rod derotation; and then all the concave screws are sequentially tightened to the rod (Figs. 105.6A and B).⁷⁴ This maneuver results in greater coronal curve correction,^{74,75} less hypokyphosis,⁷⁶ decreased LIV tilt,^{74,75} less LIV rotation,⁷⁴ higher SRS-22 self-image scores,⁷⁷ and a ~50% reduction in the rib deformity.^{76,77}

70°–100° Curves

Advance degrees of spinal curvature in AIS have often led to an anterior release to gain flexibility followed by a posterior spinal instrumented fusion. With the advent of all-pedicle screw constructs, equivalent deformity correction is achieved with posterior-only approaches and does not have a detrimental effect on pulmonary function.⁷⁸⁻⁸⁰ Alternatively, a prone thoracoscopic release can be performed with a PSF without any adverse effect on pulmonary function.⁸¹

Fig. 105.5: Thoracolumbar fusion from a posterior approach. Appropriate correction and restoration of sagittal balance with an all-pedicle screw construct from a posterior approach instrumenting the major curve from end vertebra to end vertebra.

Figs. 105.6A and B: Direct vertebral rotation (DVR): A technique for correcting the axial plane deformity. (A) As described by Lee et al., correction of the scoliosis is performed first by performing a rod rotation maneuver to derotate the spine and correct the coronal and sagittal plane deformity. (B) Then, DVR is performed at the apical vertebra on both the concave and convex pedicle screws followed by securing the concave rod to the pedicle screws.

Other techniques for larger, stiff curves include various osteotomies—Ponte, pedicle subtraction, and vertebral column resection (VCR). The Ponte osteotomy involves resection of the inferior articular processes of the cephalad vertebra and the superior articular processes of the caudal vertebra.⁸² A variation on the Ponte osteotomy, the wide posterior release, has been advocated in the L spine to improve coronal and sagittal plane correction,^{70,71,83} and some surgeons employ these techniques in the thoracic spine to gain flexibility as well. Specific techniques for

correcting kyphosis and restoring sagittal balance include the pedicle subtraction osteotomy that gains 31.7° of sagittal plane correction, and the Smith-Petersen (Ponte-type) osteotomy, which gains 10.7° of correction per spine segment.⁸⁴ Vertebral column resection is an aggressive maneuver rarely indicated in AIS, with possible consideration in curves >100°. A posterior-only approach allows three-column resection of singular or multiple vertebral segments at the apex of the deformity allowing powerful correction, albeit with significant risk.⁸⁵

OUTCOME

Adolescent idiopathic scoliosis patients who undergo PSF typically have good results—the SRS 24 has demonstrated statistically significant improvement 2 years after surgery in pain, general self-image, function from back condition, and level of activity.⁸⁶ At 5 years after surgery there was a statistically significant increase in back pain compared to the 2-year postoperative scores, and a trend toward worsening in the other four domains despite patient satisfaction scores not changing.⁸⁷ However, overall results remained improved relative to their preoperative scores. Pulmonary function is improved when a posterior-only approach is used to achieve arthrodesis.⁸⁸⁻⁹¹ The patient's ability to return to activity is related to flexibility and is statistically correlated with a lower Lenke classification, a higher SRS-22 score, and the distal extent of fusion—a stepwise decline in return to activity exists, as instrumentation is carried distally from LIV T11 to L4.⁹²

COMPLICATIONS

Preoperatively, thoughtful planning can mitigate potential intraoperative and postoperative complications. Adequate selection of levels, choosing the appropriate implants and approach, and understanding the patient's anatomy all correlate to successful deformity correction and spinal balance. Intraoperative complications are mostly related to incorrect implant placement, but can also include excessive blood loss, spinal cord perfusion problems, inadequate fusion preparation or limited bone graft, and using bulky instrumentation, e.g. crosslinks, that can lead to pseudarthrosis. Neurophysiologic monitoring with SSEPs and TcMEPs is necessary for deformity correction. The surgeon must respond to every critical change—raise patient's body temperature, ensure mean arterial blood pressure is >80–90 mm Hg, and reversing any spinal instrumentation placed or correction performed prior to the critical change.

Postoperative complications include neurovascular compromise, failure of hardware, medical issues, and wound infection. The overall complication rate in a recent SRS report was 6.3% with a mortality rate of 0.02% for all idiopathic scoliosis cases.⁹³ This is similar to an earlier SRS report in AIS patients of 5.2% and 0.03%, respectively.⁹⁴ A new neurologic event occurred in 0.75% of idiopathic cases,⁹³ which is in line with prior reports in the AIS population by Diab et al., 0.69%,⁹⁵ and Coe et al., 0.5%.⁹⁴ The infection rate from the SRS report was 1.4%.⁹³

KEY POINTS

- Correction of deformity and spinal arthrodesis is indicated in skeletally immature adolescent idiopathic scoliosis (AIS) patients with curves >45°, and >50° in skeletally mature AIS patients.
- Preoperative classification and assessment of structural and nonstructural curves aids in selecting appropriate proximal and distal levels for fusion. The Lenke classification provides the most reproducible guidance for surgical planning.
- Selective thoracic fusions are advantageous when they result in appropriate correction and spinal balance while preserving spinal motion.
- Posterior spinal fusion (PSF) with pedicle screw instrumentation affords a similar ability to correct deformity and balance the spine as anterior approaches without an adverse effect on pulmonary function.
- Safe performance of spinal instrumentation and deformity correction involves neurophysiologic monitoring with somatosensory-evoked potentials (SSEPs) and transcranial motor-evoked potentials (TcMEPs).

INTRODUCTION

Open anterior instrumented fusion for scoliosis surgery started from the use of a flexible cable by Dwyer in 1964.¹ After Dwyer cable, anterior instrumented fusion has evolved from Zielke instrumentation (a single screw/3.5-mm single threaded rod—still kyphosing and a significant incidence of pseudarthrosis) to single screw/4.5-mm single rod systems and double screw/double rod system combined with structural grafting (structural allograft vs. titanium cages).²⁻⁴ Structural graft with cages or structural allograft can produce lordotic sagittal alignment, load sharing, and allows application of compression during instrumentation. The advantages of anterior instrumented fusion of thoracolumbar/lumbar (TL/L) (type 5) curves include saving fusion levels both proximally and distally by fusing only the Cobb measurement of the curve from the upper end vertebra to the lower end vertebra.⁵ Significant rotational correction can be achieved by direct vertebral derotation and by aggressive removal of anterior soft tissues including the annulus, disc, and posterior longitudinal ligament (PLL). Solid anterior fusion also may remove the risk of crankshaft in skeletally immature patients.⁵

Anterior approach has become less commonly indicated because strong multidirectional correction using pedicle screws has changed surgical decision-making in adolescent idiopathic scoliosis. However, thoracolumbar retroperitoneal approach is still a viable option in the treatment of thoracolumbar-lumbar curves (Lenke type

5 curve). It facilitates excellent clinical and radiographic outcomes with relatively short fusion. This approach can be useful in some double major curve (Lenke type 6) with large lumbar curves and notable L4 and L5 coronal plane obliquity. After anterior instrumented fusion, improved alignment of distal unfused segments was observed. The indications for, techniques of, results and complications of, single and dual rod instrumentation for idiopathic scoliosis correction as well as comparative analysis to posterior approach will be detailed in this chapter.

INDICATIONS

Anterior thoracolumbar or lumbar instrumentation and fusion may be indicated in Lenke type 5-TL/L adolescent idiopathic scoliosis (AIS) curve when the magnitude of curve is $>40^\circ$.⁶ In addition, the TL/L portion of a double major adolescent idiopathic scoliosis with large lumbar curves in Lenke Type 3 and 6 curves may be approached with a preliminary anterior instrumented fusion prior to an instrumented posterior spinal fusion (PSF) of both curves. These indications are rare, but often performed to maximize the correction of the TL/L portion of large lumbar curves and notable L4 and L5 coronal plane obliquity with significant rotation and cosmetic malalignment.⁷

SELECTION OF FUSION LEVEL

The level of selected fusions includes all vertebrae between upper end vertebra and lower end vertebra. Sometimes

Figs. 106.1A and B: (A) Lateral decubitus position from the back. (B) Lateral decubitus position from the front.

extremely short anterior instrumentation/fusion principle by Hall/ Millis technique is helpful for very flexible thoracolumbar curves. If a vertebral body is the apex, then one disc and body above/one disc and body below are selected to be fused. If a disc is the apex, then two vertebral bodies, one disc above/two vertebral bodies, one disc below are to be fused.⁸ Sometimes choosing the lowest instrumented vertebra (LIV) at L3 versus L4 is challenging when the disc below L3 is parallel or only slightly wedged into fractional lumbosacral curve. Poor selection of L3 as LIV with a significant disc wedging at L3–L4 disc or out of gravity line (away from center sacral vertical line) may induce earlier degeneration in the future. Flexibility of lumbosacral fractional curve, the disc angle below LIV, and rotation of LIV should be carefully considered to prevent LIV with a significant disc wedging at L3–L4 disc or out of gravity line (away from center sacral vertical line) significantly.⁹

SURGICAL APPROACH

Positioning

In anterior scoliosis surgery, the spine should be approached on the side of the convexity of the TL/L curve. The patient is positioned in a lateral decubitus position and held securely in bean bag. Pressure points are padded and pillows are placed between the legs (Figs. 106.1A and B).

Exposure

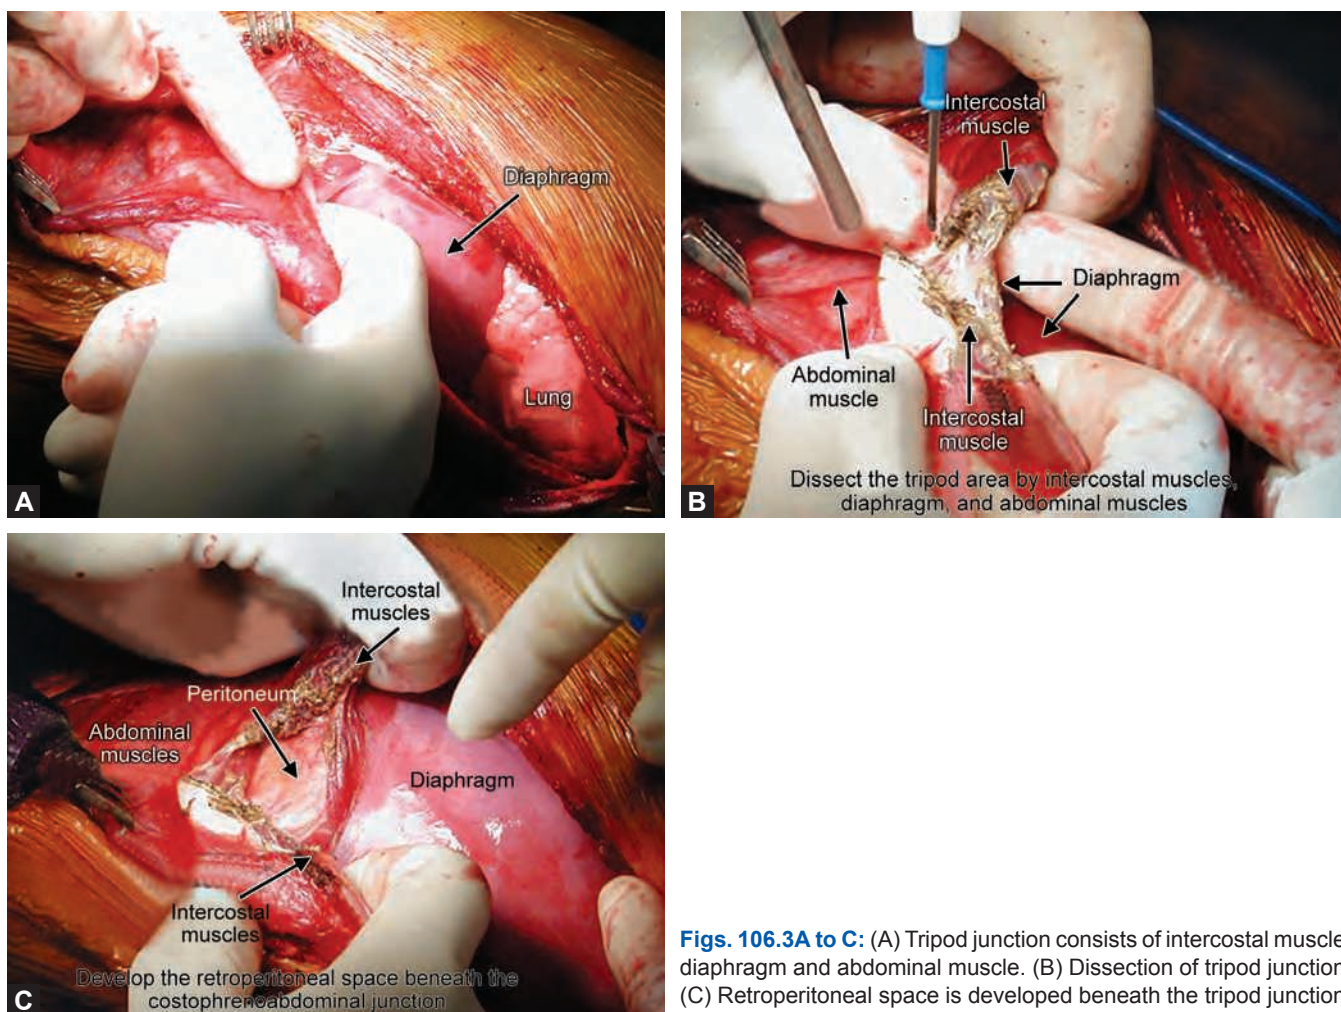

The skin incision begins in the mid-axillary line, follows the course of the tenth (or ninth) rib as far as the costal

cartilage, and then continues obliquely downward on the upper and middle abdomen, toward the lateral border of the rectus abdominus. The 10th rib may be identified by counting up from the 12th rib and is the lowest rib that is attached to chondral cartilage. After division of the latissimus dorsi and serratus anterior proximally, external oblique muscle of the abdomen that runs parallel to the skin incision from the costochondral junction area is divided to reveal the underlying internal oblique muscle. The 10th rib is exposed. The periosteum of the 10th rib is transected with the electrocautery. After complete exposure of the 10th rib, excise the rib from the costal cartilage to angle of the rib leaving no sharp edge (Fig. 106.2A). Then pack the rib bed with a gel foam or bone wax. Pick up the periosteum and parietal pleura and make a small incision with knife. Open the thoracic cavity with the Metzenbaum scissors and pack the lung (Fig. 106.2B). The costal cartilage is divided with a knife or dissected below the cartilage after a tagging suture. After dividing the external oblique muscle, internal oblique muscle, and transverse muscle of the abdomen in the direction of skin incision below the costal cartilage, carefully expose the preperitoneal fat. This is the very important entrance to the retroperitoneum and later marker for wound closure (Figs. 106.3A to C).

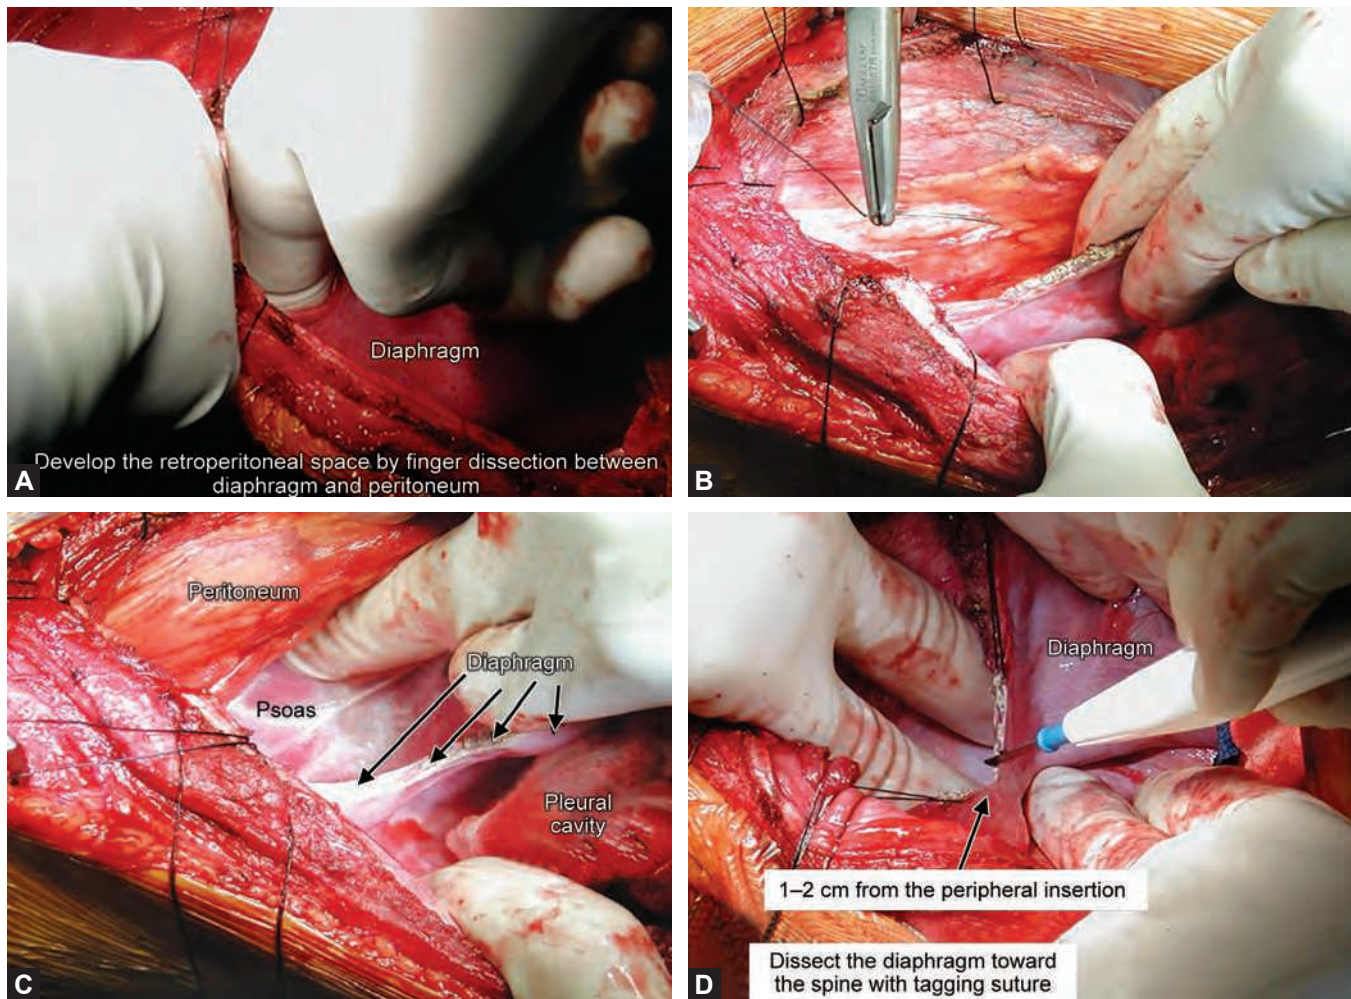

After identifying the preperitoneal fat below the abdominal muscles, retract the peritoneum medially from the lateral abdominal wall and downward from the underside of the diaphragm by using blunt dissection with gloved fingers and with a gauze on a forceps. This blunt dissection is needed toward the anterior surface of the quadratus lumborum and psoas muscles. Mobilize the peritoneum

Figs. 106.2A and B: (A) Periosteal elevator is used to detach the rib from underlying periosteum. (B) Thoracic cavity is entered by incising the parietal pleura using metzenbaum.

Figs. 106.3A to C: (A) Tripod junction consists of intercostal muscle, diaphragm and abdominal muscle. (B) Dissection of tripod junction. (C) Retroperitoneal space is developed beneath the tripod junction.

off the lateral abdominal wall and from the undersurface of the diaphragm. Under the direct vision, the diaphragm is separated to vertebral column using the electrocautery preserving a 1-cm cuff of tissue by a curved incision that follows the lateral contour of the diaphragm. Damage to the phrenic vessels and nerves can be avoided by this peripheral dissection. The diaphragm is tagged along the way with markers for later closure (Figs. 106.4A to D).

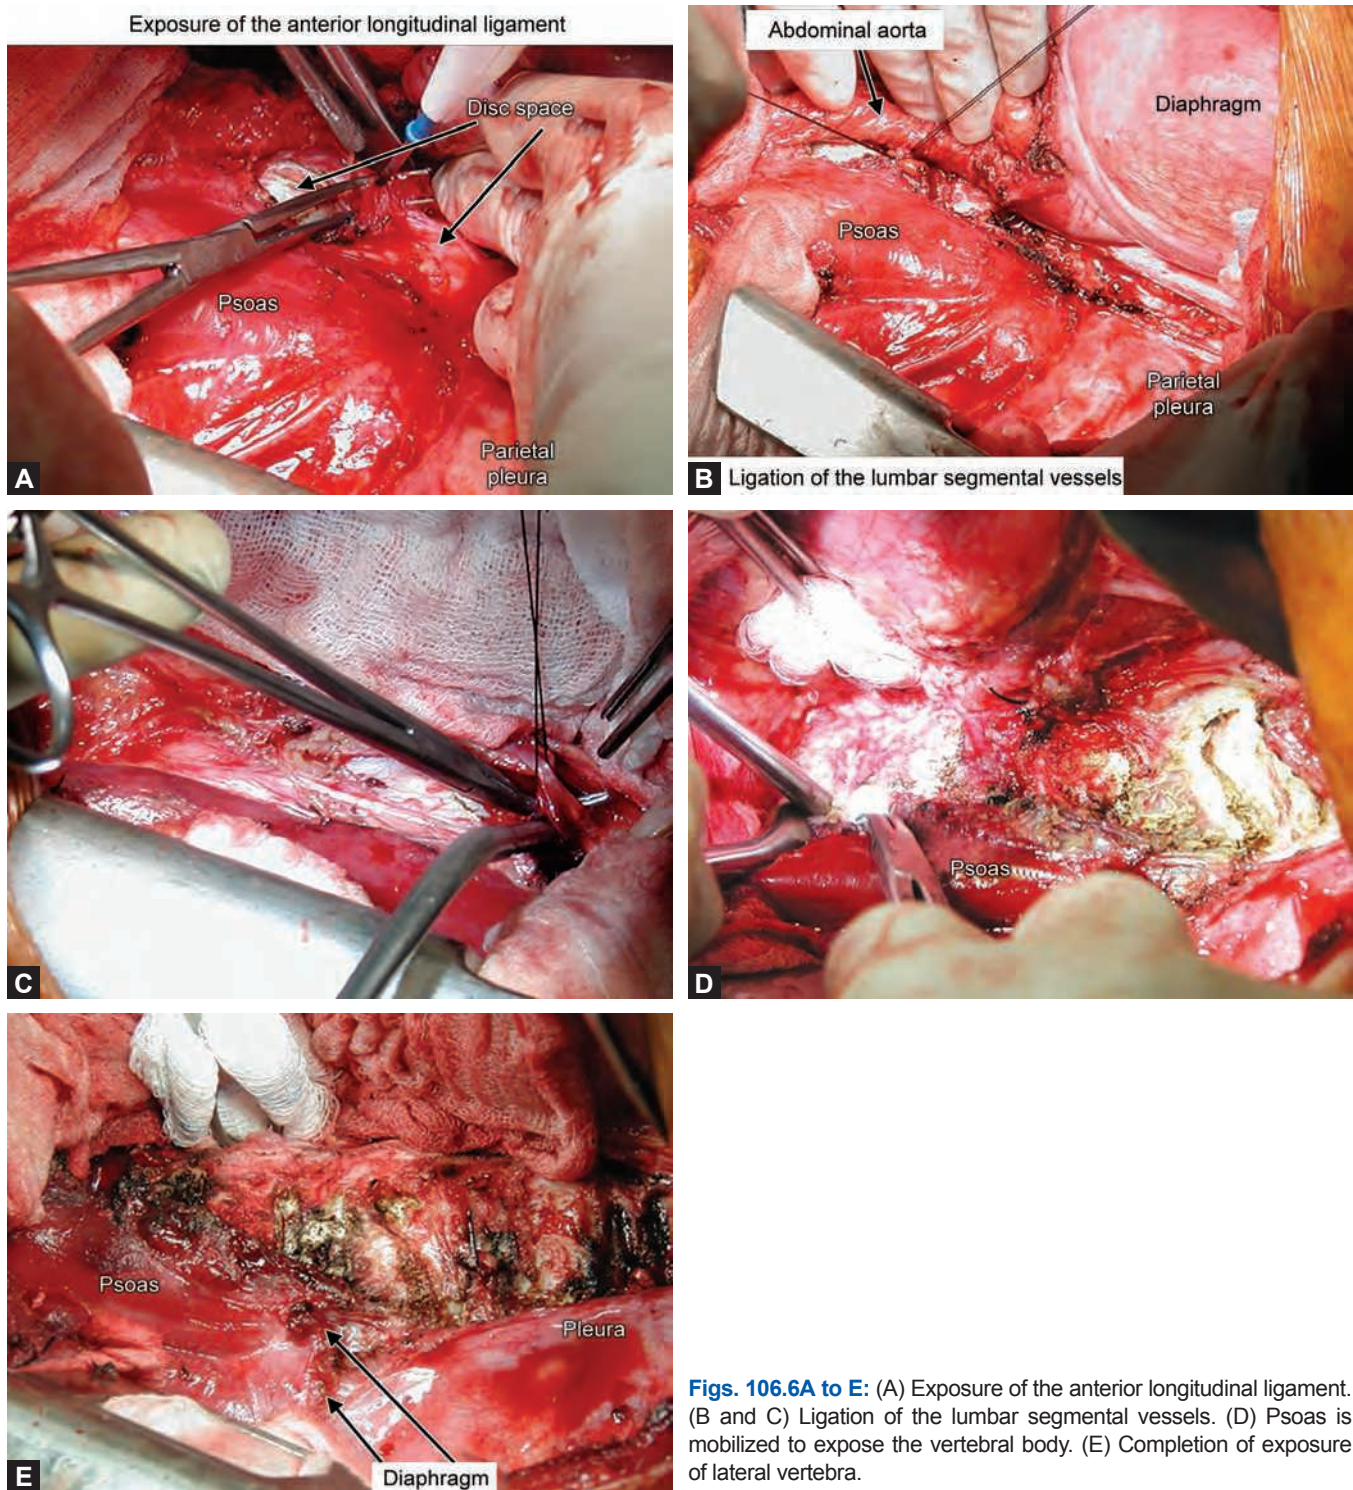

The diaphragm is incised down to the T12/L1 disc over the lateral and medial arcuate ligaments toward the crus in a radial fashion. The parietal pleura on the vertebrae to be accessed is incised with scissors along the vertebral column. The origin of the psoas major muscle is detached from the intervertebral discs and retracted posteriorly to expose the pedicle. Next the remaining abdominal muscles are divided in the direction of the

skin incision. The retroperitoneal space must be developed by the gloved finger dissection. Tagging sutures are used to mark corresponding portions of the muscle layer to help later closure (Figs. 106.5A to F).

The upper lumbar spine is exposed retroperitoneally. The peritoneal contents are swept anteriorly away from the quadratus lumborum and psoas muscle. Now self-retaining retractors can be placed to maintain the thoracotomy open and keep the peritoneal contents anteriorly. To expose the spine completely, split the parietal pleura longitudinally and ligate the segmental vessels to mobilize the great vessels. The segmental vessels on the vertebral bodies are ligated close to the aorta after detaching the psoas and cut. In the lumbar spine area, the psoas muscle should be mobilized to expose the lateral aspect of the vertebral body as far posteriorly as the base of the pedicle. Be cautious to stay in a strictly

subperiosteal plane to avoid bleeding from the segmental vessels within the psoas muscle. This type of bleeding is extremely difficult to control. At last, the spine is well exposed and the procedure can continue (Figs. 106.6A to E).

Discectomy

After exposure of the anterior and lateral aspects of the vertebral bodies to be instrumented, a thorough anulectomy and a discectomy are performed back to the PLL but not

Figs. 106.7A and B: (A) Annulectomy. (B) Discectomy and endplate preparation.

through the PLL. Care is taken to preserve the structural integrity of the vertebral endplates. A portion of annulus on the concavity was preserved to act as a hinge, to prevent overcorrection and to help hold bone graft in place (Figs. 106.7A and B).

Staples and Screws

Staples are applied to the lateral aspect of vertebral body, beginning proximally and distally and working centrally. The vertebral bodies are marked with electrocautery to identify the entry point of screws. An awl is used to create a pilot hole for the screws at mid-body, without angulation, at the top and bottom of the fusion levels. Be sure to position the staple posterior enough to allow placement of the anterior screw. Moving toward the apex of the deformity from either end, the screw entrance is developed progressively more posteriorly and is angled anteriorly to accommodate the axial rotation of the scoliosis. Each body then has a staple placed followed by a bicortical screw. Posterior screw is placed with 10° of anterior angulation, perpendicular to the base of staples. The posterior screw should be left slightly elevated off the staple's surface until the anterior screw is fully seated. Anterior screws are placed in a neutral position to place the screw perpendicular to the base of the staples. The alignment of the screws forms a relatively smooth arc, with the apex of the arc directed posteriorly. Screw placement is also determined, anticipating rod placement just posterior to the cages, to optimize lordotic contouring of the spine during compression. Bicortical purchase is especially critical at the ends of the construct where cantilever forces increase the risk of pullout.

Cages

After the screws are placed, but before the rods are secured, intradiscal bone grafting is performed at all fusion levels beginning at the most caudal disc space and working cephalad. A disc spreader is used in the posterior half of the disc space to keep the anterior half of the disc space open. The tallest structural titanium mesh cage that could be fit easily into the disc space is filled with morselized rib autograft and tapped into the anterior half of the disc space. Normally one or two cages are placed at each level. It is usually easier to insert two cages of smaller diameter (same height) rather than one larger diameter cage. The apical cages are placed in the deep concavity to allow for overcorrection of the apex in the coronal plane. In the sagittal plane, all cages are placed anteriorly in the disc to maximize lordosis. Posteriorly, morselized bone is placed against the decorticated endplates allowing for bleeding bone to contact the bone graft anteriorly, with the anterior endplates left intact to support the anterior structural grafts or cages. The disc spreader is removed, endplate decortication is performed around the cages, and morselized rib autograft is placed in the empty posterior disc space. Placement of cages at each successive cephalad disc space becomes tighter and more resistant to cage placement than the previous caudal level. This is acceptable, because when proceeding proximally, less segmental lordosis is required. Structural cages are placed at all fusion levels below T12. Fusion levels cephalad to T12 undergo endplate decortication followed by morselized rib autograft placement with the assistance of the disc spreader (Fig. 106.8).

Rods

Measurement of the appropriate rod length is accomplished by laying the flexible Bovie cord along the course of screws, marking the end with a hemostatic clamp. Make sure that it would not be too long, because the spine shortens on the instrumented side after compression. Posterior rod is contoured to accommodate anticipated coronal and sagittal alignments. During rod contouring, consideration of the desired sagittal alignment and coronal correction is made. The rod is marked at both ends to allow constant feedback for proper axial orientation during contouring, placement, and rod rotation. Rod is engaged proximally and cantilevered into the distal screws and captured at each level with set screws.

Deformity Correction

After the rod has captured all the screws, it is rotated 90° from posterior to anterior position to facilitate both

scoliosis correction and sagittal lordosis production by transforming the coronal curve into sagittal lordosis (Figs. 106.9A and B). Additionally, anterior translation of the apical instrumented levels derotates the spine. Alternatively, direct anterior vertebral body derotation can be performed. Screwdrivers are placed on the anterior screws at the apex of the construct. A direct vertebral body derotation maneuver is then performed whereby the screwdrivers and screws are then pushed down and rotated anteriorly to directly derotate the apical vertebral bodies while correcting the coronal plane malalignment simultaneously. With the vertebra being held in this derotated position, the posterior rod is engaged in the posterior set of screws, set bolts seated, and the rod is compressed from the apex to the ends (Figs. 106.10A and B). Visual inspection verifies coronal correction and sagittal alignment of the spine. Next, intervertebral compression is applied across the posterior screws beginning at the apex and working toward the ends of the construct. Gentle compression is used at the most proximal portion of the construct, because these screws are most susceptible to pullout. Intraoperative posteroanterior and lateral radiographs are then obtained to confirm appropriate placement of the instrumentation and the correction achieved. Then anterior rod is placed into screws and tightened without further attempt at correction. Lastly, the anterior rod is set in place with compression forces applied to that rod as well. Following anteroposterior and lateral intraoperative X-rays confirming optimal coronal and sagittal alignment, the set bolts are sheared off. Crosslink plates are placed to create rectangular construct for increased biomechanical rigidity. Occasionally, minor modifications of the compression

Fig. 106.8: Staples and screws are placed on the lateral vertebral body.

Figs. 106.9A and B: (A) Posterior rod placement. (B) Ninety degree rod rotation.

Figs. 106.10A and B: (A) Intervertebral compression across the posterior screws. (B) Placement of anterior rod.

or rod rotation are made to optimize correction. Care is taken to avoid overcorrection of the LIVs, which is verified by inspection of the disc alignment immediately below the LIV on the coronal intraoperative radiographs. Specifically, the goal is to have the inferior endplate of the LIV parallel to both the superior endplate of the next caudal segment and the top of the iliac crest. This is not always possible, given the residual secondary fractional lumbosacral curve. Additionally, there are cases in which the LIV is slightly overcorrected to improve coronal balance while preserving caudal motion segments. Pleural closure may then be performed, if desired, over the thoracic portion of this low profile system.

Closure

After the procedures on the vertebrae, close the parietal pleura to the original position with absorbable suture. The diaphragm is closed from the central dorsal direction toward the lateral ventral with multiple interrupted sutures of nonabsorbable suture, with care taken to reapproximate accurately using previously placed tag suture as a guide. The cartilage of the 10th rib is the landmark for the closure end of the diaphragm and meeting site to deep abdominal muscles. The internal oblique and transverse abdominus muscles are repaired as a single layer. After insertion of a chest tube with a separate stab incision, close the chest wall muscles—latissimus dorsi, serratus anterior, and external abdominal muscle layer by layer (Figs. 106.11A to E). Sometimes the rib resection gap is closed with the help of the rib approximator.

POSTOPERATIVE CARE

All patients are mobilized to stand by the bedside the day after surgery. Chest tube is kept to wall suction until drain-

age is <100 cc/shift on the 2nd and 3rd postoperative day. Ambulation is allowed as tolerated, with discharge occurring between postoperative days 4 and 7. None of the patients are braced. Activity is restricted to walking for the first 6 weeks after surgery, followed by light aerobic workouts on a treadmill or exercise bike until 6 months after surgery when the patients are released to full activity, if the spine fusion appears solid.

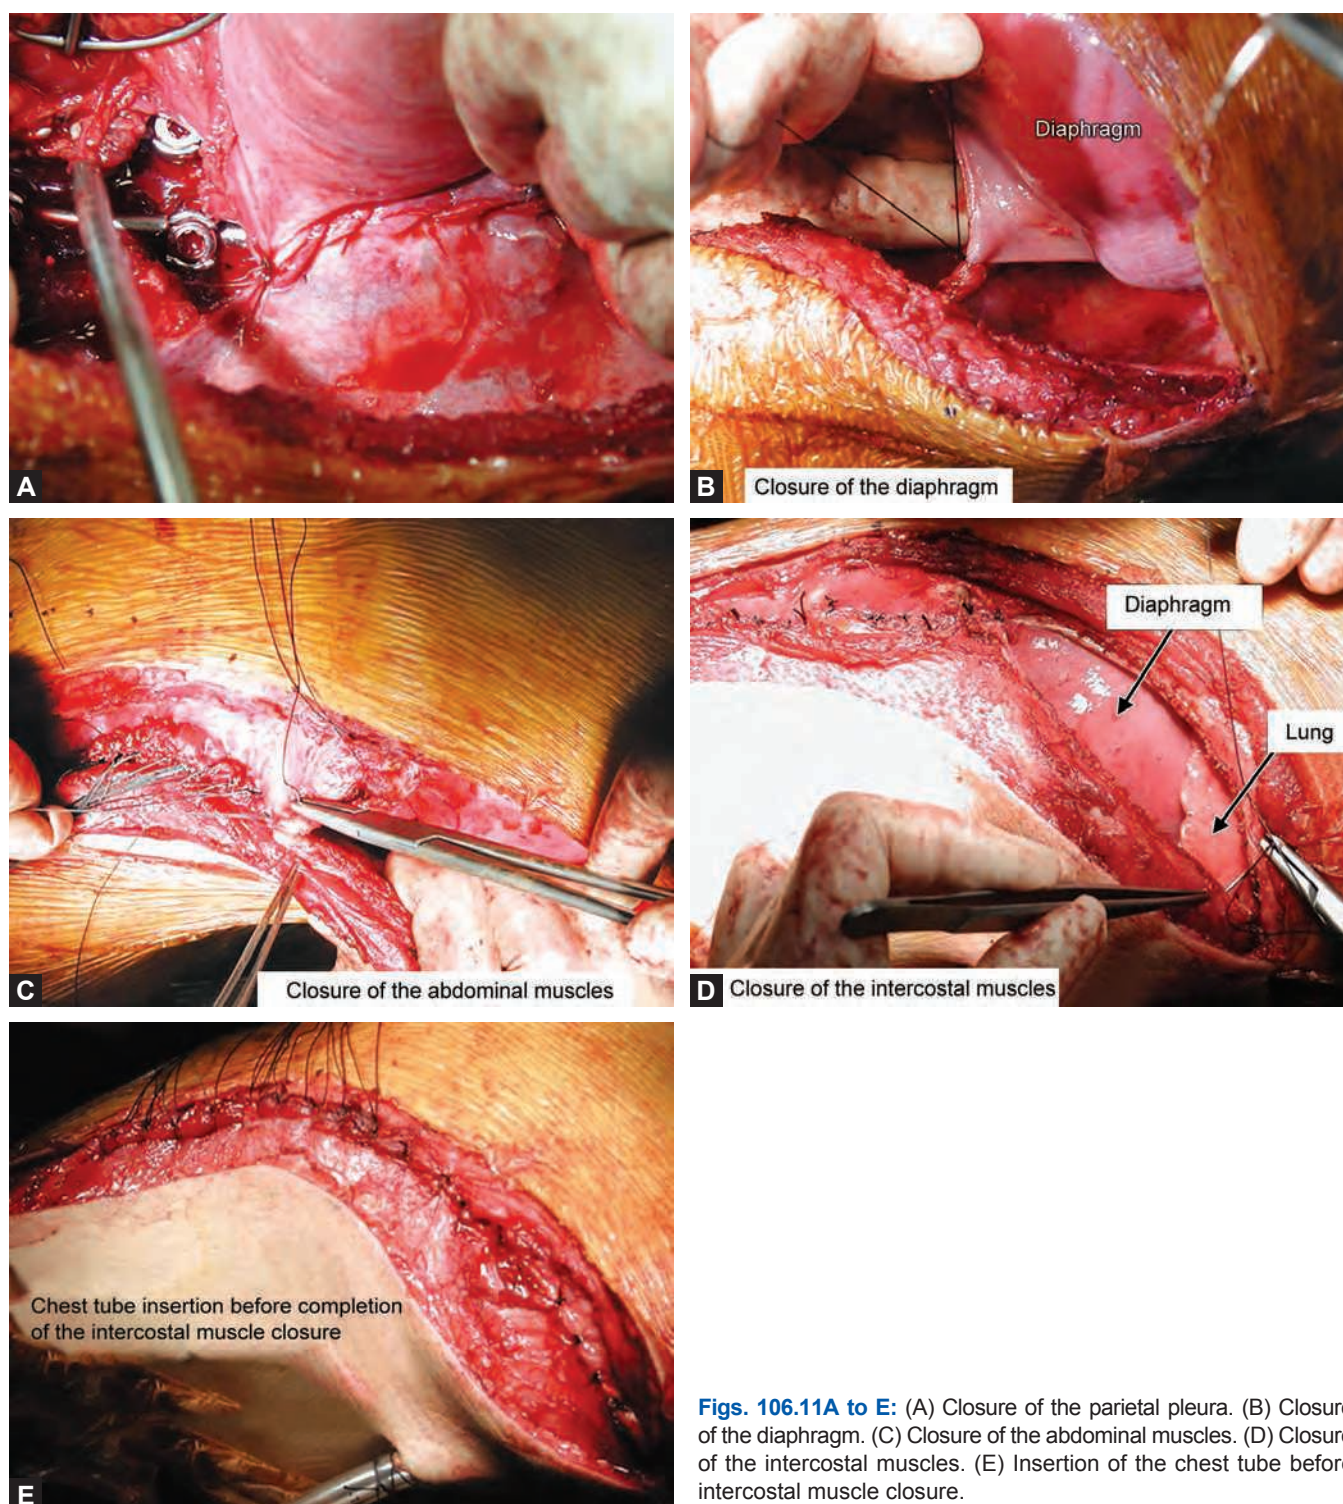

DISCUSSION

Deformity Correction

The average correction of TL/L curves varies from 70% to 80%.^{4,10} The correction depends on the curve flexibility, type of implant, reduction technique, and usage of cage. In general, outstanding correction can be achieved due to anterior discectomy and direct vertebral body derotation.

Single Rod versus Dual Rods

The benefits of the single rod include the ease and safety of single screw/rod placement to avoid the spinal canal and vascular structures. However, there are disadvantages of a single rod construct including an increased rod breakage rate and pseudarthrosis rate.^{3,5,11} A single rod is obviously less biomechanically stable, which will require bracing postoperatively in certain circumstances. Dual rods system is especially useful for larger patients or adults. As no restrictions are applied postoperatively, return to activities is quicker. It has advantage of satisfactory sagittal plane control. Dual rods have been the mainstay of treatment for scoliosis curves treated by an open procedure that allows

Figs. 106.11A to E: (A) Closure of the parietal pleura. (B) Closure of the diaphragm. (C) Closure of the abdominal muscles. (D) Closure of the intercostal muscles. (E) Insertion of the chest tube before intercostal muscle closure.

for increased biomechanical stability and an increased fusion rate.^{4,12,13} Disadvantages of the dual rod construct include difficulty in placing a dual staple and dual screws

in small patients with small vertebral bodies. However, a similar amount of radiographic deformity correction was obtained when compared to single-rod implants.¹³

Lung Function

There is concern regarding ultimate pulmonary function following open thoracotomy for anterior instrumentation and fusion procedures. Kim et al.¹⁴ showed the absolute values were unchanged but the percent predicted values were statistically less for those patients undergoing an anterior instrumentation and fusion for thoracic scoliosis curves via an open thoracotomy at 5 years postoperative. Kim et al.¹⁵ in another study demonstrated that an open thoracotomy approach for treating a main thoracic curve produces a significant decrease in the absolute pulmonary function tests values at 2 years postoperative while the thoracoabdominal approach for treating a TL/L curve did not. In addition to lung function, drawbacks related to thoracoabdominal approach are abdominal bulging, pleural effusion, ileus, and sympathectomy effect.

Pseudarthrosis

Pseudarthrosis rate seems higher with anterior-only surgery than posterior-only surgery. A single-screw/single-rod solid system reduced the pseudarthrosis rate comparing to a single-screw/single-threaded rod system. However, 6% ($n = 5$) of patients developed a pseudarthrosis with anterior single solid rod instrumented fusion for AIS.³ Common risk factors for pseudarthrosis were smoking, weight, and, for thoracic pseudarthrosis, hyperkyphosis $>40^\circ$ at T5–T12. Interestingly, SRS-22 questionnaire scores at the 2-year follow-up were not significantly different for those with pseudarthrosis versus those with a healed spinal fusion. Also, a broken single solid rod still showed apparent radiographic fusion in two of the four patients due to settling of the thoracic spine with an ultimate solid fusion with a slight increase in thoracic kyphosis postoperatively.¹⁰ Two-screw/two-rod system significantly reduces this pseudarthrosis rate.^{4,15}

Anterior Spinal Fusion versus Posterior Spinal Fusion

In comparison to posterior spinal instrumented fusion, anterior spinal instrumentation and fusion saves fusion levels by end vertebra to end vertebra.⁵ Significant rotational correction is possible by aggressive removal of anterior soft tissues. In skeletally immature patients, anterior fusion is chosen to avoid crankshaft phenomenon. It has

less chance of adjacent problem, as spinal extensor muscles are not disrupted. Sagittal plane realignment is possible by segmental compression or distraction of the disc space. Shufflebarger et al.¹⁶ showed excellent result by posterior-only approach on Lenke type 5 curve using selection of fusion level from upper end vertebrae to lower end vertebrae. Average coronal correction of the TL/L curves was from 52° to 10° (80%). In the sagittal plane, lumbar lordosis was normalized from 41° with a wide range (20° – 70°) to 42° with a normal range (34° – 47°). There were no pseudarthroses, no reoperations, no infections, no problems with screw placement, and excellent maintenance of correction at last follow-up. The LIV had 81% correction of coronal angulation; center sacral line to LIV was improved from 2.4 cm to 0.7 cm. Hee et al.¹⁷ showed that surgical correction of both the frontal and sagittal plane deformity are comparable to anterior instrumentation. Shorter lengths of surgery and hospital stay were the potential benefits of posterior surgery. Length of surgery was significantly shorter in the posterior group (189 minutes vs 272 minutes). Length of hospital stay was shorter in the posterior group (6.2 days vs 8 days). Estimated blood loss, duration of analgesia, and intensive care unit stay did not differ significantly between the two groups. Fusion levels were shorter in the anterior group (mean, 4.1 vs 5.0). Thoracolumbar sagittal alignment at T11–L2 was maintained for both groups throughout the follow-up period (Figs. 106.12A and B). The incidence of proximal junctional kyphosis was higher in the posterior group ($P < 0.01$).

Cobb-to-Cobb versus Very Short Segment Fusion versus Bone-on-Bone Technique

The Hall concept,⁸ a very short construct (three or four motion segments) with overcorrection of the apex, produced excellent coronal results. A high degree of flexibility is required for successful implementation of this approach. The candidate patient population is a relatively small proportion of patients with idiopathic lumbar or thoracolumbar scoliosis. Disc space wedging below LIV is always present due to the overcorrection of the deformity. In addition, a kyphosing effect over these segments is still an issue. Gaines et al.¹⁸ presented the technique and results achieved by limiting the instrumentation and fusion for idiopathic scoliosis $<75^\circ$ to only those vertebrae contained within the Cobb angle of the patient's scoliosis measured on the "stretch film." This allowed for

Figs. 106.12A and B: (A) SK is an 18+4-year-old female. She is very active and is dedicated professional dancer. Physical examination showed elevated right shoulder, asymmetric waist-line, and coronal decompression to the left. She had thoracolumbar (TL) idiopathic scoliosis classification Lenke 5CN. Preoperatively, the thoracic curve (T5-T10) was 38° and TL curve (T10-L3) was 55°. Isthmic spondylolisthesis was present at L5-S1. On side bending view, the lumbar curve was very flexible and corrected to 3° and the thoracic curve was corrected to 14°. Disc below L3 showed good flexibility with side benders. (B) She underwent an open anterior dual rod instrumentation and fusion from T11-L3 with anterior interbody structural support. Postoperatively, her TL curve was corrected to 20° with level shoulder with an excellent coronal and sagittal balance.

instrumentation one to four levels shorter than those used by Dr Kaneda. The instrumentation included roughly half the levels that would have been instrumented by traditional posterior segmental instrumentation. The preoperative thoracolumbar major curve was corrected from 50.5° to 18.3° (final) with fusion of four vertebrae, three discs. A spontaneous improvement of 37.4% occurred in the thoracic compensatory curve. The preoperative tilt angle improved from 27.7° to 8.3°. The sagittal and coronal balance was restored in all the patients. There were no neurologic, vascular, pulmonary, or implant-related complications. Union occurred within 3 months. All the patients returned to an unrestricted lifestyle within 4 months. Although short segment bone-on-bone instrumentation has reported good results, the placement of interbody cages at every level is recommended to maintain lumbar lordosis.¹⁹ The use of structural interbody support creates a fulcrum to increase curve correction when compression is applied to the convexity of the deformity. Biomechanical studies showed increased construct stiffness.²⁰

CONCLUSION

Anterior thoracolumbar and lumbar correction and fusion has been outstanding surgical approach to correct Lenke

type 5 or sometimes 6 curves with minimal fusion level from upper end to lower end vertebrae. Flexible cable and smaller rod has been replaced with dual rods to prevent pseudarthrosis and to support better stability. Bone-on-bone technique or bone graft without structural cage was known to have kyphogenic problem at thoracolumbar area. Cage insertion is strongly recommended to maintain lordosis in Lenke type 5. Very short segment fusion by overcorrection or bone-on-bone technique may have a limited role in small subset of patient population. Posterior approach showed many advantages over anterior approach such as faster operation time, more cosmetic, similar correction of deformity, and shorter hospital stay. However, we need more data on distal fusion level and proximal junctional kyphosis.

KEY POINTS

- Anterior thoracolumbar/lumbar (TL/L) correction and fusion is an outstanding surgical approach to correct Lenke type 5 or sometimes 6 curves with minimal fusion level from upper end to lower end vertebrae.
- Cage insertion is strongly recommended to maintain lordosis in Lenke type 5.
- Long anterior thoracoabdominal approach has drawbacks related to thoracoabdominal approach

are abdominal bulging, pleural effusion, ileus, deterioration of lung function, and sympathectomy.

- Very short segment fusion by overcorrection or bone-on-bone technique may have a limited role in small subset of patient population.
- More data on distal fusion level and proximal junctional kyphosis is needed to compare anterior approach with posterior pedicle screw technique.

INTRODUCTION

The classification and treatment of adolescent idiopathic scoliosis (AIS) have evolved over the years. Initially most surgeries were performed using a posterior approach with a combination of hooks and rods used to correct the curvature and obtain a fusion. These initial systems were prone to high rates of pseudarthrosis and often failed to address sagittal imbalance.¹ Newer systems have been developed with the use of pedicle screw-based instrumentation that have been able to overcome many of these deficits; however, these surgeries still require the fusion of multiple levels to obtain proper balance and prevent curve progression.¹⁻⁴

While less familiar to most spine surgeons, in select patients an anterior fusion offers several advantages over posterior surgery. By removing the anterior disk, the curve can be more directly addressed and better correction can be achieved with fewer levels fused. Hypokyphosis, commonly seen in AIS, can also be addressed. Additionally, once the disc is removed, the endplates provide an excellent area of obtaining a fusion.

BACKGROUND

Flexible cable anterior implants and anterior interbody correction for idiopathic scoliosis was introduced by Dwyer, and modified by Zielke.⁵⁻⁷ Anterior surgery for

idiopathic scoliosis improved correction and demonstrated that keeping the number of fusion levels to a minimum was both possible and functionally important. However, while there were many good outcomes, rod breakage, screw pull-out, and nonunions were frequent. In addition, sagittal plane imbalance, or “flatback deformity”, was not fully addressed. The stiff single-rod used in the Texas Scottish Rite Hospital (TSRH) system was found to have similar disadvantages.⁸

In response to the deficiencies of the Dwyer, Zielke, and TSRH systems, a dual-rod anterior system was developed: the Kaneda Anterior Scoliosis System (KASS; Depuy AcroMed, Raynham, MA).⁹ Kaneda reported excellent results in patients with lumbar, thoracic, and thoracolumbar scoliosis.^{9,10} These results were replicated by several surgeons in the United States, and in other countries.^{11,12} The unique feature of this treatment paradigm was that the fusion and internal fixation was limited to those vertebrae contained within the structural major curve.

PATIENT EVALUATION

All patients should undergo a thorough history and physical examination. Any history of significant back pain or rapid curved progression should be identified. The patient should be asked about any family history of scoliosis. If the patient is female, the age at which menses started should be noted. Any family history of scoliosis should be

Fig. 107.1: A preoperative plan is based on the 'traction radiograph'. The patient is laid supine on the radiograph table on a 36-inch film. Two other individuals (assistants and/or family members) then 'stretch' the patient while the patient is instructed to relax. One provides forceful but non-violent traction to the patient's upper body (neck or shoulders) while the other provides the same to the legs.

identified. A complete neurological examination should be performed, including abdominal reflexes.

Appropriate imaging studies should then be obtained. Standing full length anteroposterior and lateral scoliosis views are obtained to assess curve magnitude, sagittal and coronal balance. If there are neurological abnormalities on examination or any concerning features seen on plain films (left thoracic curve, focal scoliosis, and congenital abnormalities), a magnetic resonance imaging should be obtained.

Once surgery is indicated, there are multiple techniques for assessing the flexibility of the curve. Most commonly bending or bolster films are obtained. These films are obtained by simply having the patient bend left or right having them lean over a foam bolster. Others have advocated the use of traction films (Figs. 107.1 and 107.2). Initially these were described as being performed while under anesthesia, with manual traction being applied to the ankles and shoulders while the patient is sedated. Others have suggested that the sedation is not necessary and gentle traction while the patient is awake is sufficient.¹³⁻¹⁸

Preoperative pulmonary function tests should be obtained when considering an anterior approach. If there are any abnormalities, consideration should be given to converting to a posterior approach.

Fig. 107.2: An example of the 'stretch' radiograph. A type 5 curve measuring 53° on erect radiograph (left), 'stretched' out to 26° (right), based on the principle of a gentle stretch of the trunk (center).

■ INDICATIONS/CONTRAINDICATIONS

The Lenke classification system is currently the most commonly used system for AIS. Adolescent idiopathic scoliosis patients with Lenke I (thoracic main curve) and Lenke 5 (thoracolumbar curve) may be amenable to an anterior approach. The main curve should be <85° and the compensatory curves <50. The structural curve should correct to <50° on bending, traction, or stretch views. Limited use of this technique could be considered in patients with double or triple major curves; however, in generally, these would be best served by a posterior approach. When an anterior approach is used for patients with double or triple curves only the major curve should be corrected and the goal should be to balance the remaining curves. Patients should be approaching skeletal maturity and should be Risser stage 2 or greater (Table 107.1).

An anterior approach should be avoided in patients with neuromuscular scoliosis, impaired pulmonary function, extremely large curves (>85°), or in whom there are other contraindications to an anterior approach. In general, this approach should be avoided in skeletally immature patients (Risser <2) who have juvenile scoliosis (Table 107.2).

■ SURGICAL TECHNIQUE

Preoperative Planning

Once the appropriate films are obtained and the decision is made to proceed with an anterior approach, a surgical

1. Idiopathic scoliosis
2. Single major curves (Lenke types 1 and 5)
3. Major curve with Cobb measurement < 85°; thoracic modifier N or -.
4. Major and compensatory curves 50% flexible or reduce to 30° on 'stretch film'
5. Risser sign > 2

Table 107.2: Contraindications for anterior short segment fusion.

1. Abnormal preoperative pulmonary function tests
2. Infantile and Juvenile idiopathic scoliosis.
3. Most neuromuscular scoliosis
4. Many double major curves, proximal thoracic structural curves
5. Large (>85), stiff curves (less than 50%) flexible on the 'stretch film'
6. Risser < 2

Fig. 107.3: An example of a preoperative blue print: The fusion levels are determined using the stretch radiographs. The Cobb levels are identified on the stretch radiograph. The convex (158 cm) and the concave (129 cm) chord lengths are determined from the respective corners of the Cobb vertebrae. The individual disc heights are added on the concave (21 cm) and the convex sides (45 cm). Subtracting the disc heights from the corresponding chord lengths gives us the measure for the corrected heights of the convex and the concave columns. A value <5 mm between the convex and the concave sides would lead to a satisfactory correction as shown diagrammatically.

plan is developed. This is based on the bending or traction films (Fig. 107.3). The Cobb levels are identified. The cords length on the convex side is obtained by measuring the length from the superior corner of the cephalad vertebra in the Cobb to the inferior corner of the caudal vertebrae. The individual disc heights on the convex side are then measured and added together. This number is then subtracted from the cord length on the convex side. The same process is then repeated on the concave side. The difference between the numbers on the concave and convex sides should be within 5 mm. If the difference is >5 mm additional levels may need to be included.

Fig. 107.4: Positioning the patient in the right lateral decubitus position on a peg board. This secures the patient throughout the procedure.

Positioning and Exposure

The patient is first positioned on a peg-board on a radio-lucent operating table (Fig. 107.4). Neuromonitoring, including baseline somatosensory-evoked potentials and motor-evoked potentials should be established. For constructs that will end to T11 or below, an extrapleural, retro-peritoneal exposure is performed. The 11th and/or 12th rib may be removed to help with exposure. A thoracotomy is performed when the instrumentation is going to extend more proximally. At each level, the segmental vessels are isolated, ligated twice with vascular clips and then transected. The levels that are to be instrumented are then exposed including the transverse processes and rib heads. The rib heads at the appropriate thoracic levels are then removed. An osteotomy is created through the neck of the rib between the costotransverse and costovertebral joints. Removing the rib-head exposes the costovertebral joint and the neural foramen. The remaining peripheral rib articulates at the costotransverse joint.

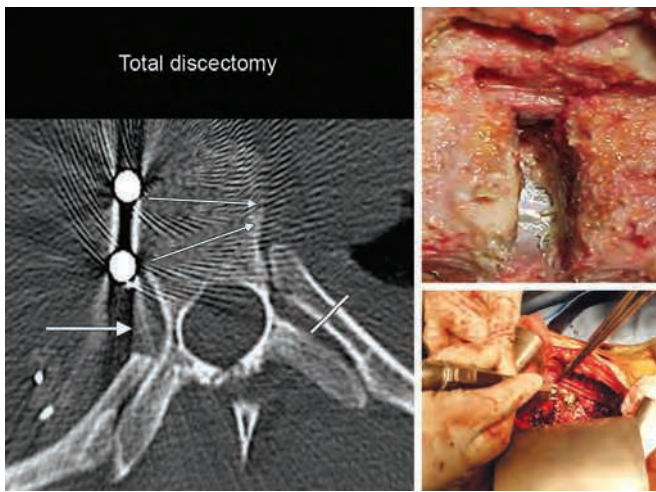

Fig. 107.5: Excision of the rib head (right bottom) allows for a safe identification of the posterior extent of the disc, and safe placement of the instrumentation (left). Performing a “total discectomy” at each level in the apical levels of the curve (right top) is central to the success of this procedure.

The neural foramen is then identified. Precise awareness of the location of the foramen is essential, as it guides the surgeon to the spinal canal and protects the neural structures. A curved curette is used to carefully expose the foramen. Once adequately exposed, a Penfield dissector is placed into the spinal canal through the intervertebral foramen and anterior to the spinal cord. The posterior aspect of the intervertebral disc is palpated. This identifies the posterior annulus, and confirms the interval between the posterior annulus of the involved vertebra and the thecal sac. Epidural bleeding is controlled by thrombin-soaked gel foam, applied through the foramen.

Thoracic Discectomy and Endplate Preparation: The Bone-on-Bone Technique

The intervertebral discs are then resected at the levels determined in the preoperative plan. The discectomy should be performed at the most apical level first and then continued to the caudal and cephalad levels. This approach permits better visualization of the more peripheral discs with increasing correction. In general, the straighter the spine, the easier the disc space is to visualize and the more straight-forward the discectomy. The disc material can be removed using Cobb's, curettes, pituitaries, and rongeurs. All the disc tissue must be removed until the two vertebrae begin to collapse toward one another. On the concave side, the posterolateral corner on the contralateral side and the posterior annulus (and

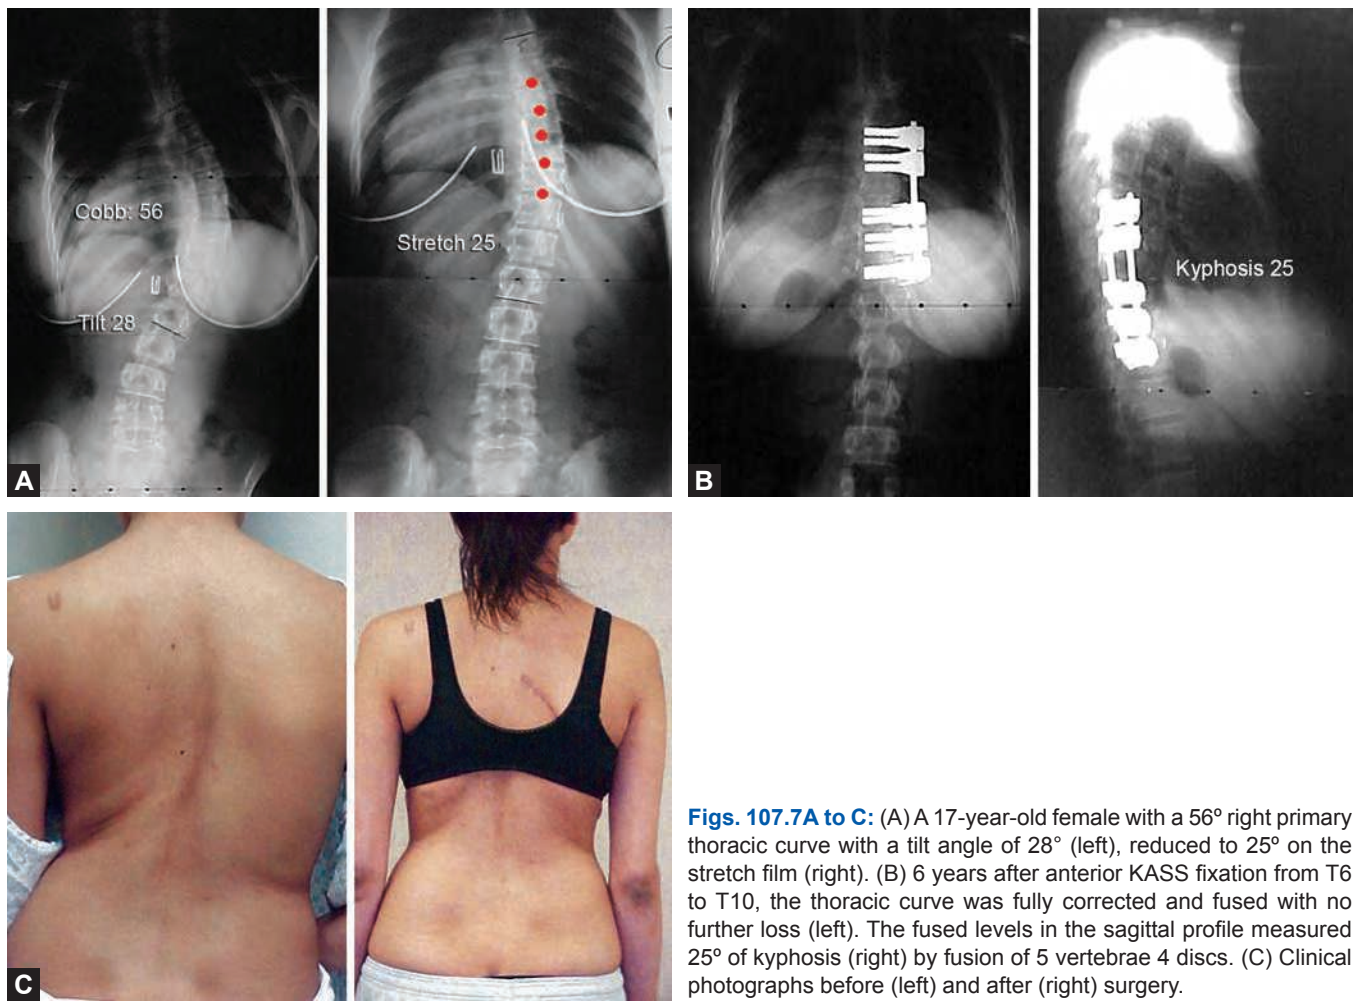

Fig. 107.6: A complete discectomy is followed by bone-on-bone apposition. This corrects the deformity in all three planes. The end plate apposition is demonstrated. Bone-on-bone inter-body contact leads to a favorable position for the fusion.

the posterior longitudinal ligament) must be removed using Kerrison rongeur or a sharp straight long-handled rongeur. The cartilaginous endplates are removed while the bony endplates are left intact. If necessary a small portion of the peripheral endplate on ipsilateral side can be removed to allow for better visualization. If there are voids in the endplates auto or allograft chips can be used to fill them. Once the interspace closes with good bone-on-bone apposition, gel foam is placed into the disc space to help decrease bleeding. Attention is then turned to the next disc space (Figs. 107.5 and 107.6).

After all the discs are excised, a “repositioning maneuver” is performed. This is done by stretching the patient, while the anesthesiologist or an unscrubbed assistant lifting the torso and gently pulling the lower shoulder upward. This may help with curve reduction.

An appropriate sized vertebral body staple is then selected and placed in the center of the vertebral bodies over the segment of the spine to be instrumented. Fluoroscopic imaging is then used to assess the coronal plane correction of the major curve; the positioning of the vertebral body staples; the correction of the tilt angle; and sagittal plane correction. Any adjustment regarding selection of fusion levels is made at this time. Perfect placement of the staples is essential for proper screw placement. The staples function as a “screw-guide”. Two triangulated vertebral body screws then provide a stable vertebra-implant interface. The screws should have bicortical purchase, especially the screws at the ends of the construct.

Figs. 107.7A to C: (A) A 17-year-old female with a 56° right primary thoracic curve with a tilt angle of 28° (left), reduced to 25° on the stretch film (right). (B) 6 years after anterior KASS fixation from T6 to T10, the thoracic curve was fully corrected and fused with no further loss (left). The fused levels in the sagittal profile measured 25° of kyphosis (right) by fusion of 5 vertebrae 4 discs. (C) Clinical photographs before (left) and after (right) surgery.

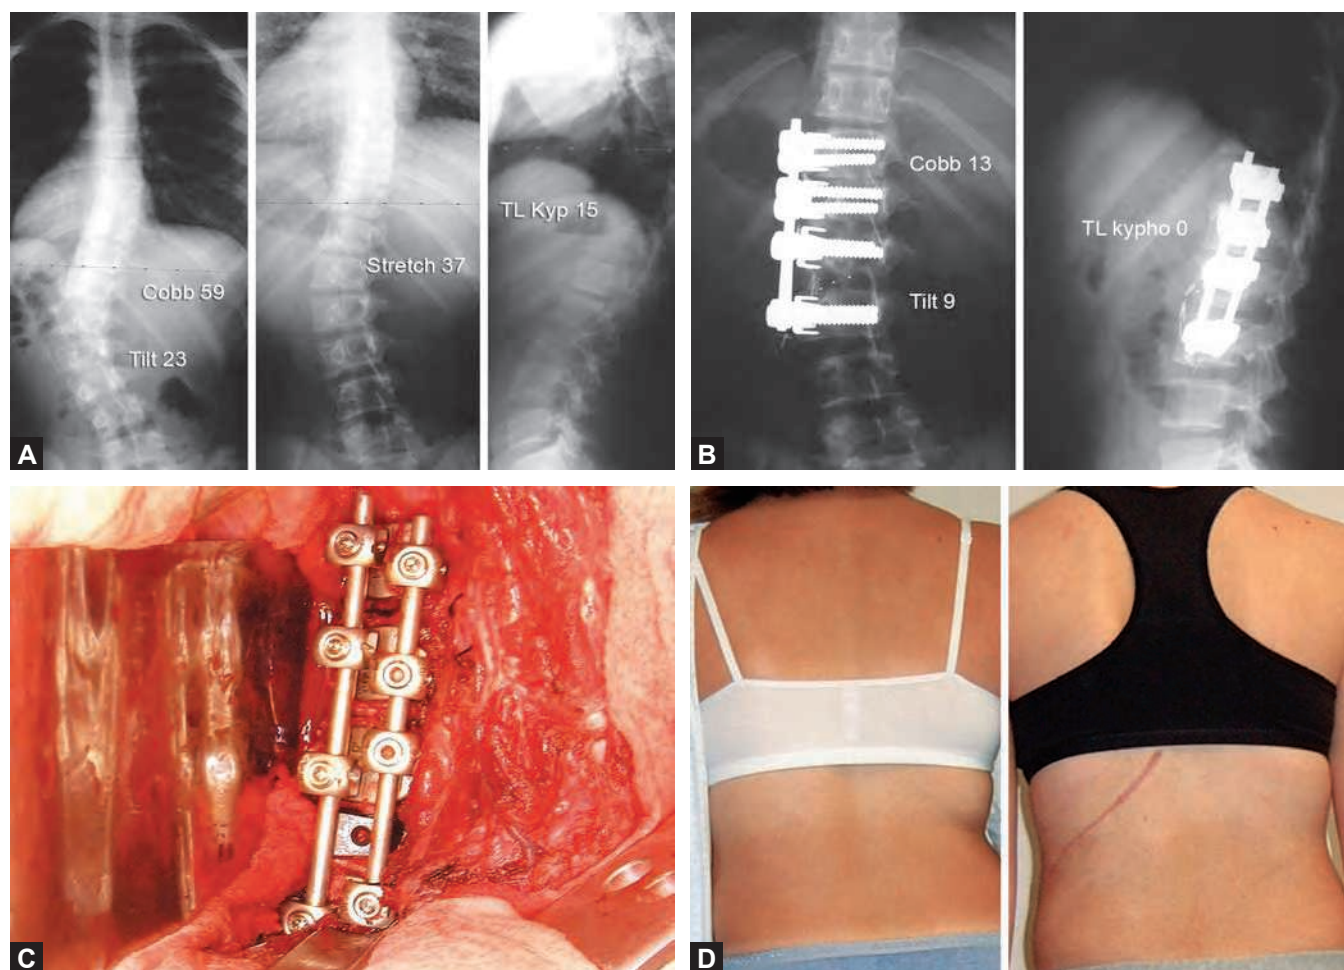

Once the screws are properly placed, an assessment is made about the length and contour of rods necessary to both correct the curve and also restore ideal sagittal plane alignment. Once that assessment is made, the rods are selected and bent if necessary. The first rod is placed into the screws and secured with caps. At each level a compressor is used to bring the peripheral vertebrae toward the apex. A Penfield dissector is used to palpate between the adjacent vertebrae to ensure that bone-on-bone apposition is being achieved. The second rod is then inserted into the second set of screws. No additional correction is achieved with the second rod and it is used primarily to improve rotational stability.

Clinical examples of both coronal and sagittal plane correction appear in Figures 107.7 to 107.10.

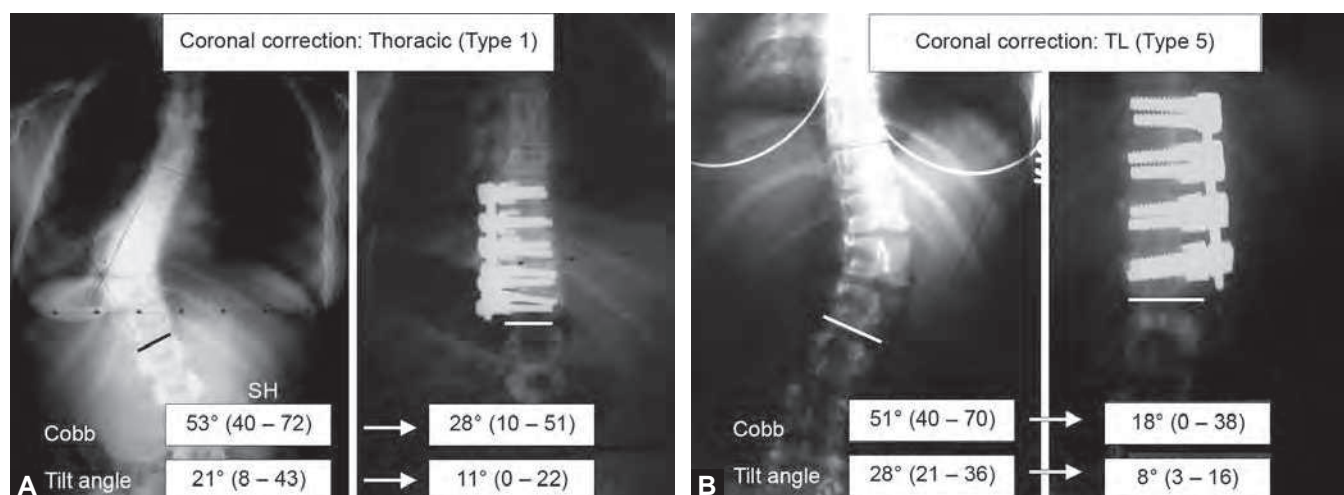

For Lenke type 5 curves that extend below T11, interbody cages may be used to help restore lordosis. The intraoperative assessment of the sagittal profile—by both clinical

inspection and intraoperative X-ray or fluoroscopic imaging guides the need for cages. These cages are inserted using a standard technique for lateral interbody cages. Bone graft, either iliac crest or allograft should be placed in the cages. The screw/rod construct should include all levels into which lateral interbody cages have been placed as well as all of the proximal levels where the bone-on-bone discectomy has been performed.

At the completion of the case, an epidural catheter can be placed into the intervertebral foramen at the top of the construct to help provide postoperative analgesia.¹⁹ For cases involving a thoracotomy, the parietal pleura or a Gore-Tex pericardial patch is then sutured over the rods and screws to serve as a barrier between the instrumentation and the lungs. A chest tube is also placed and set to suction. Routine muscle and skin closure is then performed. If thoracolumbar instrumentation is performed with the extrapleural-retroperitoneal approach, no chest drain or other drain is necessary (Table 107.3).

Figs. 107.8A to D: (A) A 19-year-old female with a 59° type 5 curve with a tilt angle of 23° (left) with a thoracolumbar junctional kyphosis measuring 15° (right), stretching to 37° (center). (B) This was corrected by T12 – L3 instrumentation and discectomy to a Cobb of 13° and a tilt angle of 9°. The thoracolumbar junctional kyphosis was corrected by placing a cage at L23, and a bone on bone apposition at the other levels. (C) Intraoperative picture after the correction and instrumentation. (D) Clinical photographs before (left) and after (right) surgery.

Figs. 107.9A and B: The results of coronal correction of type 1 curve (A) and type 5 curves (B).

Figs. 107.10A and B: The results of the sagittal correction of type 1 curve (A) and type 5 curves (B)

Table 107.3: Tips and tricks for short segment fusion for scoliosis.

1. Patient must be securely placed in lateral position on a peg board or similar table
2. If the proximal instrumented level is below T11, an extra-pleural retroperitoneal approach can be performed
3. If a transpleural approach must be performed, there is no need to deflate the lung. Careful retraction is enough for a wide operative field
4. The foramen must be identified in order to excise the posterior annulus. This allows the vertebrae to collapse one toward the other, with a bone on bone apposition
5. The discectomies proceed from the apical disc toward the ends of the curve to facilitate exposure of the more peripheral discs.
6. Although the authors prefer a dual rod system, this technique does not rely on the implant for success. BONE ON BONE—following “total discectomy” at each operated level is the key factor.
7. BMP, allografts or bone substitutes are not required with the bone-on-bone technique.
8. Thoracolumbar curves (Lenke type 5) may require the placement of a cage below T11 to assure anatomic reconstruction of the sagittal profile.

POSTOPERATIVE CARE

Following surgery patients are generally kept in the intensive care unit. Depending on the patient and the facility, this may be for as little as 24 hours or up to 4–5 days. If placed during surgery, the epidural catheter can be used for pain control. This is weaned by the 3rd or 4th day after surgery. If no epidural catheter was placed, then a patient-controlled analgesia pump with intravenous pain medications is used. Patients are gradually transitioned to oral pain medicines. The chest tube is first placed to suction and then to waterseal. Serial chest X-rays are taken to ensure that no pneumothorax develops. If there is no

pneumothorax while on waterseal, the tube can be discontinued, generally by the 3rd or 4th day postoperatively.

Early ambulation and mobilization are encouraged. Patients should be out of bed within 24–48 hours of surgery. Generally back braces are not necessary although a corset style brace may provide some pain relief. A more rigid brace can be used at the surgeon's discretion or if there were any concerns about fixation during the surgery.

After discharge from the hospital, the first month following surgery is focused on rest and allowing time for healing. Physical rehabilitation proceeds after the first month to restore the patient to his or her usual activities. School children are back in school by 6–12 weeks following

the surgery, and working adults are back to work, at least part-time, within 6–8 weeks.

RESULTS

Initial reports on the outcomes of selective anterior fusion were concerning. Bernstein and Hall²⁰ reported on a series of 17 patients with thoracic curves, all had excellent curve correction (87%) that declined slightly at 24 months (67%). During surgery three patients had problems with placement of the instrumentation that required additional levels to be fused. There were no reported pseudarthrosis or instrumentation failures.

Betz et al.¹ reported on a larger series of 178 patients with primary thoracic curves, 100 of whom were treated with posterior fusion and 78 with anterior surgery. They found similar correction of coronal curves (58% for posterior vs. 59% for anterior). Anterior surgery was better able to address hypokyphosis (81% of patients with hypokyphosis were corrected to within 20°–40° compared to only 19% with posterior surgery). Hyperkyphosis however was much more prevalent after anterior surgery, occurring 40% of the time when preoperative kyphosis was ≥20°. An average of 2.5 fewer levels were fused using an anterior approach; however, higher rates of complications were also reported in this group. Patients treated with an anterior approach had higher rates of pseudarthrosis (5% vs. 1% in the posterior group), loss of correction (23% vs. 12%), and implant breakage (31% vs. 1%). The anterior procedures utilized a flexible rod system, which explain the higher rates of implant-related complications, pseudarthrosis, and loss of correction seen in this study.

Later studies demonstrated better results. Smith et al.²¹ reported on a series of 15 patients followed radiographically for an average of 44 months and clinically for 61 months. They reported a 66% correction of the major thoracic curve and 40% and 61% spontaneous improvements in proximal and distal curves, respectively. They noted no change in sagittal alignment. At final follow-up, they reported a modified Social Responsiveness Scale (SRS) score of 4.3 out of 5 (average of all five domains). They also reported an overall patient satisfaction rate of 88%. There were no cases of pseudarthrosis or implant failure. Two patients developed adjacent segment disease below the fusion resulting in spinal stenosis and radiculopathy. One patient developed proximal degeneration. Additional studies continued to show good curve correction for tho-

racic curves (47–71%) with a relative low rate pseudarthrosis and implant-related complications.^{9,10,12–14,22,23}

Several studies have also directly compared anterior and posterior fusion techniques. Muschik et al.²⁴ directly compared patients undergoing anterior and posterior approaches. In their series, 104 patients underwent posterior fusion for AIS and 37 were treated with an anterior approach. All patients had primary single thoracic curves. They noted similar correction of the coronal curves and hypokyphosis (T4–T12 <20°). For patients with hyperkyphosis (T4–T12 >40°), a posterior approach was able to achieve some correction while less correction was seen in anterior surgery; however, the difference between the correction from the two approaches did not reach statistical significance. There was an equal rate of complications between the two groups (approximately 12%). Importantly, they did note that anterior surgery requires four fewer segments to be fused.

The efficacy of anterior fusion for thoracolumbar curves has also been studied. Bitan et al.²⁵ reported on a small series of 24 patients with thoracolumbar curves treated with anterior surgery. Five of these patients had Harms cages placed into the intervertebral space. They reported a 59% correction of the lumbar curve and a 21% correction of the compensatory curve. On an average 2.9 levels were fused. Two patients were noted to have a pseudarthrosis, and one had a loss of fixation. These are similar to the results seen by Kusakabe et al.¹⁴ who reported a 64% correction in Lenke V curves treated with anterior fusion. They also noted a 37.4% spontaneous correction of the thoracic curve.

Geck et al.²⁶ compared 62 patients with Lenke V curves, half were treated with and anterior surgery and the remainder using a posterior approach. They noted significantly better results from posterior surgery, including better initial curve correction (84% vs. 67%), less loss of correction over time (3.4% vs. 9.4%), better correction of lumbar lordosis (17% vs. 0), and shorter average hospital stay.

The long-term outcome following anterior fusion of Lenke V curves was reported by Sudo et al.^{27,28} They followed 30 patients for a mean of 17.2 years. They reported a 79.8% correction with 3.4% lost over time. Twenty-three percent of patients were noted to have degenerative changes at the levels above the fusion. Two patients required extension of the fusion, one for thoracic curve progression and one for disc wedging. At follow-up, the mean SRS-30 was 4.2 when averaged overall five domains.

COMPLICATIONS

Many of the complications reported after anterior surgery for scoliosis are similar to those for any major surgery and include ileus, urinary tract infection, surgical site infections, misplaced hardware, and wound healing issues.^{1,14,20-22} Additional complications have been reported related to patient positioning. Betz et al. reported skin breakdown from an axillary roll, while Seraph et al. had one case of brachial plexopathy.

Hardware failure and pseudarthrosis were more commonly seen in earlier studies. Intraoperative hardware failure has been reported and has led to additional levels needing to be fused.^{20,24} Late hardware failure may be associated with pseudarthrosis. Rates of pseudarthrosis range from 0% to 5%.^{1,14,23} Sweet theorized that risk factors for pseudarthrosis include smoking, weight >70 kg, and hyperkyphosis.

Major vascular injuries have not been reported; however, Betz did report of an injury to a segmental vessel that required reoperation.¹ Segmental vessels are of particular concern as they provide the blood supply to the spinal cord. The largest of these vessels, the artery of Adamkiewicz, generally originates on the left side between T9 and T11. Disruption of this artery or even some of the smaller segmental vessels may affect the blood supply to the spinal cord. This is a relatively rare event (1.1% of anterior surgeries²⁹), but can be potentially devastating. It has been theorized that patients with hyperkyphosis, intraspinal anomalies, or who are undergoing revision surgery may be at higher risk. The artery can be temporarily occluded to see if there are any changes in neuromonitoring. If there are no changes, it can be assumed that the artery is safe to ligate.

In addition, there have been reports of approach related complications. Thoracolumbar approaches put at risk the lumbar plexus, genitofemoral nerve, and sympathetic chain. Brodner et al. reported on a series of patients undergoing surgery for both thoracic and thoracolumbar curves.¹³ Of the 11 patients treated for thoracolumbar curves, they noted four cases of anterior thigh numbness that they attributed to retraction of on the ilioinguinal and/or genitofemoral nerves during the procedure. They also noted five cases of what was termed a "sympathectomy effect" following the surgery, which they described as being a "nuisance" only and did not require any further intervention.

Anterior surgery for thoracic curves invariably involves disrupting the pleural cavity and the associated

risks. Commonly reported complications include pneumothorax and pleural effusions.^{1,20,24} Patients with scoliosis are already predisposed to decreased pulmonary function and anterior surgery may exacerbate this. Kim et al.³⁰ have evaluated the effect of spinal fusion on pulmonary function in patients with scoliosis. They noted significant decreases in forced expiratory volume in 1s (FEV1) and percentage predicted forced vital capacity (FVC) in patients who had anterior surgery at 5 years. Patients with posterior-only surgery had a slight increase in FEV1 and no change in FVC. Lonner et al.³¹ noted similar decreases with anterior procedures and found greater changes in patients undergoing open thoracotomy as opposed to thoracoscopic procedures. Newton et al.³² predicted that 50% of patients undergoing an open thoracotomy will have a 15% or greater decrease in their pulmonary function at 2 years. In contradiction to these studies, Verma et al.³³ noted only minimal changes in pulmonary function at 2-year that did not vary significantly between anterior, posterior, or thoracoscopic approaches.

SUMMARY

Short segment anterior fusion provides a safe and effective option for the treatment of selective patients with AIS. Careful patient selection is essential. Eligible patients should have Lenke I or V type curves measuring <85°, with secondary curves <50°. Consideration should also be given to sagittal balance. While anterior surgery may help correct the hypokyphosis commonly seen in patients with AIS, it may accentuate hyperlordosis and should be used with care in these patients. Careful preoperative planning is essential and bending or traction films should be utilized to select the levels to be included in the fusion. Initial surgeries were complicated by relatively high rates of implant failure and pseudarthrosis; however, this has decreased with newer surgical techniques and implant designs. While the surgery remains technically demanding, studies have shown excellent long-term results with fewer levels fused compared to comparable posterior surgery and a similar rate of complications.

INTRODUCTION

Spondylolysis and spondylolisthesis (SL) are reported to be the most common causes of structural low back pain in children and adolescents.¹ Spondylolisthesis is defined as the anterior translation of one vertebra over another, most commonly involving the lumbosacral junction. “*Spondylos*” is the Greek word for vertebra, and “*listhesis*” means to slip or slide. This deformity frequently originates from stress fractures, or small cracks, in the pars interarticularis (pars). These stress fractures often result in spondylolysis, which is a defect of the vertebral arch, specifically the pars. With a weakening of this posterior buttress, there is greater tendency for the vertebra to sublux out of place. Wiltse et al. originally described six major classifications of spondylolysis based on etiology, identifying congenital or dysplastic (involving dysplasia present at birth), isthmic (pars stress fracture or instability), degenerative (arthritic), traumatic, pathologic (tumor or infection), and postsurgical.² Isthmic is the most common variety of SL in the skeletally immature patients. Regardless of the etiology, the condition often progresses to a final common pathway: forward slippage of one vertebra on the one subjacent.³

Spondylolysis leading to SL often occurs during the first and second decades of life. The majority of patients with spondylolysis and SL are pain free, and therefore

are unaware of their condition. Symptomatic adolescents typically present with associated lower back pain and weakness or numbness, depending on which spinal nerves have been affected. No major progression of the disease is generally seen after this period; however, in middle age degenerative SL becomes more prevalent. The quality of life in patients with spondylolysis and those with low-grade slips is comparable to that in the normal population, whereas high-grade listhesis tends to progress and can cause disability in a relatively higher proportion.³

Knowledge of the natural history of the disease may help when determining treatment options. Conservative management is generally the standard of care for low-grade subluxation, with surgical treatment reserved for high-grade SL.

EPIDEMIOLOGY

The incidence of SL in children has been reported by Fredrickson et al. to be ~4%, increasing to 6% in adulthood.⁴ Hensinger examined ethnic differences, finding that the incidence in Caucasian males is higher than that among black females; however, high-grade listhesis occurs four times more frequently in females than in males.⁵ Rowe and Roche explored the variance of SL in demographic groups, finding an incidence of 6.4% in white males, 2.8% in black males, 2.3% in white females, and 1.1% in black females.⁶

Other studies have similarly found incidence disparities between ethnicities; at an extreme, spondylolysis rates as high as 54% can be found among certain Eskimo populations.⁷ Differences in rates of SL based on location have also been observed, with 82% occurrence of SL at L5–S1, 11.3% at L4–L5, 0.5% at L3–L4, and <0.5% at L2–L3.⁶

Beutler et al. followed a cohort of 500 patients for 45 years to help define disease history.⁸ By age 6, 22 patients were diagnosed with SL or spondylolysis. After a 45-year follow-up, a total of 30 patients, or 6% of the total studied population, had pars lesions. Their results suggest that the clinical course of the pathology is typically benign, and that the subluxation is mostly stable; after 20 years, progression was seen in <40% of patients with a listhesis. There was no correlation between pars defects and pain, and only 15% of individuals with a pars defect developed SL. Additionally, none of the patients with unilateral pars defects developed listhesis. Many patients, including some with high-grade slips, were asymptomatic, and the authors concluded that the disease may be largely underreported due to the lack of symptoms. Patients with low-grade SL have a lower rate of progression compared to those with a higher-grade slip. Patients who have a higher grade of SL as well as greater lumbosacral kyphosis and higher slip angle were also found to have a higher risk of progression.^{9–11} In an archeological and anatomic study of two different ethnic groups (Aleut and Arikara Plains Indians), Whitesides et al. found a higher frequency of spondylolytic SL with decreased sacral table angle in homogenized groups, which suggests a genetic component to SL etiology.¹²

Adult progression of SL is most closely related to degenerative changes in the intervertebral disc. As degeneration progresses and the disc space collapses, symptoms may develop associated with advancing listhesis. However, symptoms are not always associated with disease progression. Floman reviewed 18 patients with known asymptomatic SL who developed severe symptoms due to disc degeneration at the level of the slip, and found progression of subluxation to range from 9% to 30% in affected patients.¹³ In a retrospective long-term study of surgically and conservatively treated patients, Seitsalo et al. found an association between the natural history of SL and degenerative changes; the magnitude of listhesis was positively correlated to the degree of disc degeneration in the olisthetic segment. This group also found a correlation between the number of degenerated discs or the degree of degenerative disc disease and low back pain symptoms.¹⁴

However, spontaneous stabilization of the olisthetic segment was observed in the majority of the patients, leading the authors to speculate that the natural history of SL is benign.¹⁴ In a review of adult spondylolytic and SL patients in Finland, Virta found that 33% of patients progressed to >10% slip, although no correlation of these findings with symptomatic low back pain was observed.¹⁵

After a cross-sectional review of 4,151 patients from the Copenhagen Osteoarthritis Study Group, Sonne-Holm et al. determined that spondylolysis may proceed to SL in adulthood. Notable risk factors for this progression included increased age and higher body mass index (BMI) in women, and increased lumbar lordosis and decreased pelvic inclination. In men, lumbar SL was associated with higher BMI and increased lumbar lordosis, but not aging. Pelvic inclination and lordotic angle were found to be individual risk factors for lumbar spondylolysis.¹⁶

Sports and other activities undoubtedly can cause or further progression of SL in some patients, increasing the incidence from the 6% to 8% rate seen in the normal population. Much higher rates have been observed among individuals who participate in high-impact sports, including gymnastics, rowing, and football.¹⁷

■ PATHOGENESIS

A wide variety of pathological processes may result in an abnormal lumbosacral junction. The etiology of many of these pathologies is still not well understood, and is currently a matter of debate and study. Various classifications have attempted to discriminate between these etiological processes, to help determine optimal treatment strategies. As previously described, associated risk factors for slip progression in the immature spine include the following:

- Female gender
- Presentation at younger age
- Severity of slip at presentation
- Dysplastic type (congenital dysplasia of the sacrum or L5 vertebral arch)¹⁸
- Increased slip angle or lumbosacral angle.

The slip angle and lumbosacral angle have been evaluated by Dubousset, who concluded that these angles were the most accurate predictors of disease progression.¹⁹ Marchetti and Bartolozzi aimed to classify disease based on etiology, concluding that dysplastic bony structures may be the cause of a more aggressive and evolving type of deformity.²⁰ Pawar et al. studied 131 patients with developmental SL, and found that in the normal population,

88% had no or mild dysplasia, while most patients with low-grade (62%) or high-grade (73%) SL had moderate or severe dysplasia, respectively.²¹ This report further described six criteria for assessing dysplasia.²¹ In 2005, Herman and Pizzutillo added to the Marchetti-Bartolozzi classification, categorizing developmental SL as old pars fractures.²² Pizzutillo also studied the patients and families with SL, and noted a hereditary component in 28% of cases, which was often found incidentally. In this group of 70 patients and 222 first-degree relatives, isthmic defects were consistently more frequent than the dysplastic variants.²³

In the last decade, several papers described a variety of spinopelvic parameters, with associated etiological importance to developmental SL.²⁴⁻²⁶ In many reports, pelvic incidence was observed to be higher in spondylolisthetic patients. Since pelvic incidence is a specific, non-variable parameter unique to the individual, a high pelvic incidence correlates with a high sacral slope, thus increasing shear forces through the lumbosacral junction. While sacral slope may gradually increase for Meyerding grades 1, 2, and 3, it was observed to decrease in grades 4 and 5.²⁷ Vialle et al. surmised that this phenomenon was due to diminishing contact with the sacral endplate leading to sacral and pelvic retroversion.²⁷ Vialle et al. also observed that SL patients in general have increased sacral slope, pelvic tilt, and lumbar lordosis as well as a decreased thoracic kyphosis, concluding that the lordosis was secondary to the high pelvic incidence and therefore related to high shear forces in the pars.²⁷ A rounded sacral dome also predisposes to progression of slip in the presence of a lumbosacral deformity. Additional research involving radiographic parameters is recommended to better define the significance of these factors, specifically in defining prognosis. Thus, this spinopelvic parameters seem to have strong correlation with clinical and surgical outcomes.

CLASSIFICATIONS

This complex group of pathologies has been classified both by anatomical characteristics (Meyerding and Wiltse) and by etiology (Marchetti and Bartolozzi).^{2,20,28,29} The Meyerding classification is based on the degree of displacement of the superior vertebra over the inferior segment as visualized in a lateral radiograph. Grade 1 is defined as <25% displacement, grade 2 from 26% to 50%, grade 3 from 51% to 75%, and grade 4 from 76% to 99%. Although 5, is not part of the original classification system, it is reserved for the complete slippage of the upper vertebrae; Spondyloptosis.

Table 108.1: Wiltse-Newman anatomic classification, recently updated with a type VI.

Wiltse-Newman spondylolysis classification

Type I	<i>Dysplastic</i>	Olisthesis due to congenital defect
Type II	<i>Isthmic</i>	Pars interarticularis lesion, due to stress fracture (subtype A), elongated and intact pars (B) or acute fracture (C)
Type III	<i>Degenerative</i>	Chronic intersegmental instability
Type IV	<i>Traumatic</i>	Injury causing fracture in areas beyond the pars
Type V	<i>Pathological</i>	Olisthesis due to bone disease
Type VI	<i>Iatrogenic</i>	Post-surgical

The Wiltse classification divides SL into five types, with type II often divided into subtypes based on the acuity of the pars lesion. The dysplastic type involves congenital dysplasia in the sacrum or L5 vertebra. In isthmic SL, the basic lesion is a pars defect, differentiated as intact, elongated, or fractured/lysed. Type III is characterized as degenerative, and types IV and V are from traumatic and pathological etiologies, respectively (Table 108.1). A type VI category was later added, referring to an iatrogenic (postsurgical) etiology.²

The Marchetti classification distinguishes between developmental and acquired types. Developmental type is divided into low- and high-grade dysplasia, although the differentiation between these dysplastic types is unclear. Acquired SL is secondary to trauma, surgery, pathologic disease, or degenerative processes. The traumatic form is due to acute injury or stress fracture. Stress fractures are often sports related, and may be distinguishable from developmental etiology by the absence of dysplastic changes (Table 108.2 and Fig. 108.1).²⁰

In 2005, Herman and Pizzutillo proposed a new classification specifically for the pediatric population, combining the Wiltse and Marchetti systems.²² The authors proposed that dysplastic be considered one category, and that type II (developmental) refer to a child that was diagnosed incidentally and secondary to a pars defect, excluding primary defects. The traumatic category was divided into acute and chronic fractures; the latter included a pars stress reaction, stress fracture, or spondylytic defect. The final classification, type IV, was pathological. Reliable treatment algorithms have been based on this combined algorithm, with type I patients typically receiving strict

Table 108.2: Marchetti classification based on etiology.

Marchetti-Bartolozzi spondylolysis classification

Developmental	High dysplastic: lysis, elongation Low dysplastic: lysis, elongation
Acquired	Traumatic: acute fracture, stress fracture Pathological: local, systemic Postsurgical: direct, indirect Degenerative: primary, secondary

follow-up and possible surgical candidates, types II and III indicating mostly conservative treatment, and some slight modifications for type IIIB cases.

Mac-Thiong also proposed a pediatric classification system, based upon dysplastic changes and sagittal spinopelvic balance.²⁴ This description focuses on guidelines for surgical management, considering sagittal balance restoration as one of the main goals for treatment of all types of SL, regardless of etiology. Mac-Thiong divided the disease into three main groups: low grade (Meyerding 0, 1, and 2), high grade (Meyerding 3 and 4), and spondyloptosis. These categories are further divided then separated into low and high-dysplastic subtypes, and further divided based on sagittal spinopelvic balance. Use of the Marchetti classification is recommended for communicating with patients, as it comparatively minimizes medical jargon. The Scoliosis Research Society has adopted the Marchetti classification as the recommended system³⁰; however, the Mac-Thiong classification is recommended for surgical guidelines and the Herman-Pizzutilo classification for conservative management. Each classification system has associated advantages, and until a comprehensive and treatment-based algorithm has been developed, it is recommended that all criteria be taken into consideration during management decision making.

CLINICAL PRESENTATION

Patients with SL may never seek medical attention because the pathology is often asymptomatic. Those who do seek care can present with a variety of symptoms; however, lower back pain is the most common complaint. The treating physician must attempt to elucidate the underlying cause of the pathology.

Medical History

The managing clinician should be aware of the following³¹:

- *Past medical history:* Birth details, neurologic or metabolic disease, hyperlaxity, or any other relevant previous history must be taken.

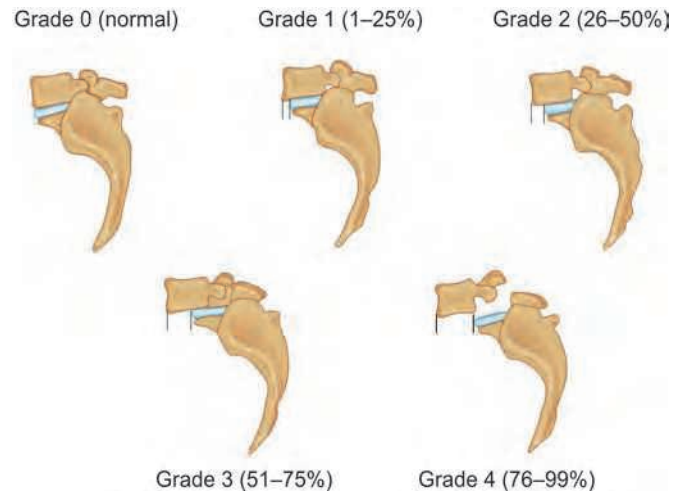

Fig. 108.1: Meyerding grading system for spondylolisthesis.

- Onset and history of pain.
- *Characteristics of pain:* Related to sport activities, worse with sitting or standing, episodic or continuous, intensity of pain, local back tenderness, or associated with irradiating pain to buttock or posterior thigh (note that most young patients do not have classic root tension signs).
- *Duration of pain:* Pain with longer history is more likely related to spondylolysis than new-onset pain.
- *Traumatic factors:* A specific traumatic event or specific sports including gymnastics or swimming. Classical symptoms include the following³²:
- *Mechanical lower back pain:* Pain exacerbated with motion such as sports and similar activities and not painful at rest. This pain occurs due to abnormal load transfer across the vertebral endplates and disc, specifically where the degenerative process begins. Pain may come from the inflammatory process near the lytic site. This may be the reason why facet and lytic site injections can alleviate pain. The intensity and frequency of painful events are highly variable, and depend on many factors. In adults, there is a trend toward increasing pain related to degenerative disc changes; however the evidence for this is conflicting.
- *Leg pain:* Most children will not present with the classical symptoms of radicular as pain described in adult populations. Irritated nerves present as tenderness in the posterior thigh, with associated pain, numbness or tingling. These symptoms, if present, are worsened with exercise and do not subside at rest. It is very unusual to

find motor or sensory deficits, or neurogenic claudication. In children, compensatory mechanisms for this pain include lumbar muscular spasms, diminished leg straightening, and forward bending. In a study of 415 patients, Lafond found that only 25% of children with spondylolysis or SL experienced pain before 20 years of age, and about 9% sought medical attention.³³ Most high-grade SL develops during adolescence, typically when the patient becomes symptomatic.^{5,25,34}

- *Phalen-Dickson sign*: This has been described as an abnormal gait characterized by tight hamstrings, bent knees, and flexed hips. The clinician may also notice exaggerated lumbar lordosis and more prominent buttocks. If associated with herniated nucleus pulposus, make sure to be on the lookout for radicular findings and possible bowel/bladder control findings. Usually present in high-grade SL, pain appears in adolescence and can have a combination of symptoms including the following:
 - Sciatic pain
 - Vertical sacrum and pelvis
 - Lumbosacral kyphosis
 - Tight hamstrings
 - Abnormal pelvic waddling gait.

Physical Examination

The physical examination may range from that of a classic presentation to no significant findings. In spondylolysis and in low-grade SL, there are often no clinical signs to make a diagnosis, and back pain may not appear during the clinical examination. Some may have minimal pain with extension or flexion, although these may be irrelevant or related to other common causes of lower back pain in children. In high-grade disease states, more specific signs appear. Therefore, a typical static posture with a lumbar kyphosis, tight hamstrings, and variable lordosis in the lumbar spine provides the classical presentation of these children.

Depending on the degree of slippage and pain, children and adolescents may present with the following characteristics:

- Hyperlordosis of the lumbar spine
- Sagittal misalignment (lumbosacral “step off” on palpation of spinous processes)
- Deviation of the trunk

- Flexed knees (for compensation of horizontal sacrum)
- Tight hamstrings (reflecting some root irritation)
- Paraspinal muscle spasm (depends on pain present)
- Gait disturbances (high grade and ptosis, also L5 root entrapment)
- Sensorimotor deficits (high grade, nerve root impingement)
- Bowel or bladder dysfunction (extremely rare)
- Associated scoliotic deformity, occurring in some patients.

Pain provocation with different movements (i.e. flexion for discogenic pain or extension with facet joint pain) is not a reliable measure for diagnosis. In the differential diagnosis, specific pathologies commonly diagnosed in childhood should be considered. These may include neurofibromatosis, Marfan’s syndrome, Ehlers-Danlos syndrome, myelomeningocele, and osteogenesis imperfecta.

Diagnostic Workup

After clinical evaluation, imaging is essential to fill in gaps from the physical examination. Unfortunately, there is a sparse correlation between pain and radiologic changes. Thorough conservative treatment based upon imaging and physical examination, in conjunction with judicious surgical indications, is essential for adequate treatment.

Radiographic Examination

Collimated lateral and true anteroposterior (AP) angled radiographs will provide necessary findings. On lateral films, the displacement, slip angle, sacral dome deformity, and L5 morphology are examined. The pars defect is also sometimes identified; on AP films, it is possible to find a pars defect along with the “Napoleon hat” sign in high-grade slips. On oblique radiographs, the pars defect is observed with a pathognomonic “Scotty Dog Collar” sign. Full-length films including the pelvis are essential to evaluate associated deformities, spinopelvic parameters, and sagittal balance. This important evaluation is necessary for surgical decision making. The chronicity of the pars lesion may be anticipated in the presence of sclerotic margins.

There are several ways to measure the translational displacement and severity of slip in SL, as seen Figures 108.2 and 108.3.³⁵ The importance of this measurement dilemma cannot be overstated, as most surgical decisions are made from this finding; description of severity of slips, prognosis, and decision-making all utilize the Meyerding grading system for assessment.

Figs. 108.2A and B: Anteroposterior film demonstrating the classic signs on X-ray. (A) Oblique view, arrow points to the Scotty Dog Collar. (B) Shows the inverted Napoleon Hat sign.

Figs. 108.3: Two different spondylolisthesis measurement techniques. Technique 1 uses the b–f line perpendicular to the S1 endplate (line e–d), whereas, technique 2 uses a tangent to the L5 posterior wall, line a–b. These lines indicate the position of L5 on S1 in point f.

Other important measures include the following:

- Percent of anterior displacement³⁶
- Slip angle; as described by Boxall et al.³⁷
- Percent of rounding on top of sacrum.

These three measurements are described to be valuable in estimating the risk of slip progression in children.^{9–11}

Bone Scan

While SL is often diagnosed with radiographs, bone scans are particularly useful in the diagnosis of spondylolysis. Bone scanning is a useful tool for two main purposes: demonstrating the presence of a pars hypermetabolic

Table 108.3: Treatment algorithm for suspected spondylolysis based on SPECT bone scan and radiology results.⁴¹

<i>Radiology</i>	<i>SPECT</i>	<i>Interpretation</i>	<i>Action</i>
Negative	Negative	Other cause	Consider MRI, look for other diagnosis
Negative	Positive	Probable active lesion	Begin conservative treatment (rest, bracing). Order CT scan
Positive	Negative	Inactive, old lesion	Consider surgical treatment to prevent progression. Investigate back pain further.
Positive	Positive	Active pars lesion	Begin conservative treatment (brace and rest). CT scan for prognostic factors.

(SPECT: Single photon emission computed tomography; MRI: Magnetic resonance imaging; CT: Computed tomography).

activity (mechanical stress or fatigue fracture) and determining the age of onset of the pars lesion. Single photon emission computed tomography (SPECT) bone scans are particularly helpful as they more precisely determine radioactive accumulation and demonstrate a transverse reconstruction of the vertebra.³⁸ Standard radiographs, including oblique views, may produce false negatives, resulting in a persistent doubt of the diagnosis. The SPECT bone scan is preferred over computed tomography (CT) scans to avoid the large radiation dose. Single photon emission computed tomography also enables the treating physician to determine the following^{39,40}:

- The precise localization of the lesion to focus CT scan (if necessary)
- Age of the pars lesion
 - High signal activity lesions suggest healing potential and treatment is advised.
 - No signal activity suggests lack of healing potential, indicating an alternative management course.

A potential algorithm for managing back pain in children in whom a spondylolysis is suspected based radiologic examinations is discussed in Table 108.3.

CT Scan

The best study for bone is a CT scan. This is an essential imaging study for spondylolysis and SL. Particularly in spondylolysis, the clinician should be aware of the possibility of a false-negative study. This may occur when the gantry is positioned perpendicularly to the pars defect. Gantry angle for these studies must be arranged parallel to the pars interarticularis.⁴² With multislice CT scans, one can reconstruct the spine in any desired plane, allowing the precise anatomy of the pedicles and the shape of the spinal canal to be observed, to best determine the presence and degree of compression.⁴³ Also the profile of the foramen can be revealed, with information including vertebral body displacement, posterior arch dysplasia, L5 trapezoidal shape, and the S1 characteristics.⁴⁴

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) may not be appropriate for evaluating spondylolysis, although it can aid in the diagnosis of SL. This can display characteristics of the olisthetic segment, the study of nerves structures, disc, cauda equina, endplate abnormalities, and facet joint arthritis. Bone edema in the pars suggests metabolic activity, and may indicate the age of the pars lesion. Magnetic resonance imaging may detect edema that a CT may miss, which can lead to a “prelysis” lesion diagnosis, and subsequent treatment.⁴⁵ In high-grade SL with associated neurologic symptoms, MRI is indicated.^{46,47}

Disc degeneration, modic endplate changes, and disc herniations at the olisthetic level may be indications for MRI use. However, MRI has been associated with a high rate of false-positives and a low positive predictive value for pars defect detection.⁴⁸ The study is more commonly used to rule out other causes of back pain, mainly adjacent level disease, herniated discs, and intraspinal tumors. The specific degree of compression on the exiting nerve root can be well visualized with MRI. Use of gadolinium may be helpful, as special sequences for radiculography may show radicular dysfunction.

CT Myelography

While MRI has largely surpassed myelography in diagnostic preference, indications for myelography include the following:

- Contraindications for MRI, including implanted devices such as a pacemaker
- Functional stenosis, mainly dynamic subarticular or foraminal stenosis, which may only be diagnosed by this method
- Postoperative or iatrogenic SL.

It is important to note that independent myelography is of limited significance, and should be performed in conjunction with a dynamic study and CT Scan (i.e. myelo-CT).

Provocative Discography

The use of discography has been controversial for some time, and is no longer part of the diagnostic armamentarium of tests useful in determining the status of the adjacent level disc. The utility of this diagnostic tool has no proven effect on the outcome of surgery, and there are a variety of different factors that may affect the results. For further information, please refer to the Carragee study on discography.⁴⁹

TREATMENT

Nonsurgical Management

Spondylolysis and Low-grade SL

Nonoperative treatment of spondylolysis or low-grade SL is often grouped together as the disease history and outcomes after management are so similar.^{50,51} In a study by Micheli and Wood, pars stress fractures without cortical disruption were observed in 47% of athletes.⁵² In these patients, CT or bone scans were often positive although radiographs were negative (Table 108.3). These lesions may be unilateral or bilateral, with unilateral fractures having a greater chance of healing. In the Beutler et al. study, all unilateral pars fractures healed.⁸ Bilateral stress fractures may heal, although in Beutler's series, no bilateral lytic defects were found to have adequately healed. Sys et al. reported healing of bilateral fractures in elite athletes if treatment was started early, stressing the importance of timely diagnosis on outcomes.⁵³ It should be noted that with bilateral stress fractures, differences in healing may be determined by the etiology of the defect. Traumatic or sports-related injuries are more prone to heal than other types of lesions, whereas old or chronic lesions (seen as hypoactive on imaging studies) were not found to adequately heal. Despite the sparse results in healing, ~90% of these elite athletes were found to return to their previous level of activities.⁵³ This benign natural history in most patients, and the temporal possibility for healing, creates a challenge in treatment decisions. Operative treatment for all patients is unrealistic as the vast majority of surgeries may be unnecessary. On the other hand, delaying surgical treatment will result in diminished rate of healing in the remaining nonhealing group, due to the progressive defect. There is currently a lack of literature regarding risk factors for continuous clinical symptoms in spondylolytic patients, suggesting the need for additional study.

The Cavalier review suggests that early brace treatment is associated with better outcomes than if initiated after a failed trial treatment with sports restriction and anti-inflammatory drugs plus physiotherapy.^{50,54} Some studies have examined the use of different types of corset, although these are based upon few cases with short follow-up. Turner and Bianco recommended a 6-month period of full day corset,⁵⁵ while Blanda et al. used a full day orthotic for only 2 months, followed by an exercise program, yielding an 82% rate of successful treatment in 28 symptomatic patients.⁵⁶ The treating physician should evaluate the psychological implications of a long-term treatment with corsets. Overall, a 75% positive outcome may be expected for spondylolysis and low-grade SL.⁴² Steiner and Micheli⁷⁸ described use of a modified Boston brace with an extension to the thigh for 6–12 weeks as a valuable treatment option.⁴² The rationale behind the thigh extension is to diminish the flexion/extension movement on the lumbosacral junction and to allow bony bridging across the pars defect.

The rehabilitation process should include the following five steps:

1. *Halt inflammatory process:*
 - a. Brief bed rest for 24–48 hours
 - b. Anti-inflammatory drugs for 5–7 days
 - c. Pars anesthetic/steroid block
2. *Enhancement of muscle strength:*
 - a. Isometric in horizontal plane and neutral spine position
 - i. Avoid extension
 - b. Trunk motor control
 - c. Strengthen antigravitational muscles
3. *Flexibility:*
 - a. Hamstring muscle stretching
 - b. Lumbar fascia stretching
 - c. Protected range of lumbar movements. Avoid lumbar extension
4. *Aerobic training:*
 - a. Cross-training (bicycle, elliptic, and hydro gym)
5. *Return to play:*
 - a. Steps 1–4 accomplished
 - b. Sports-related motor control
 - c. Hamstrings adequately stretched
 - d. Aerobic conditioning related to the specific sport
 - e. Progressive return.

Regardless of the rehabilitation process used, individual variation in training and goals should be provided.

Approximately 85% of patients with low-grade SL are asymptomatic and will not require treatment. Patients may

Table 108.4: Treatment guidelines based on etiology.⁵⁷

Etiology	Age	Low grade (Meyerding I-II)		High grade (Meyerding III-IV)		
		Asymptomatic	Back pain only	Back and neurologic symptoms	Back pain only	Back and neurologic symptoms
Developmental	Children	No treatment	Mostly nonoperative	Surgical	Surgical	Surgical
	Adults	No treatment	Mostly nonoperative	Mostly surgical	Nonoperative or surgical	Surgical
Degenerative	Adults	No treatment	Nonoperative or surgical	Usually surgical	Nonoperative or surgical	Usually surgical
Postsurgical	Children	No treatment	Attempt nonoperative	Surgical	Surgical	Surgical
	Adults	No treatment	Attempt nonoperative	Surgical	Surgical	Surgical
Pathologic	Children	Depending on etiology	Depending on etiology	Depending on etiology		
		Depending on etiology	Depending on etiology	Depending on etiology		
Trauma	Children	Depending on etiology	Surgical	Surgical		
	Adults	Surgical	Surgical	Surgical		

become symptomatic after three or four decades in association with disc degeneration, as stated previously in this chapter.

Indications for conservative treatment in low-grade SL include the following:

- No neurologic deficits
- Tolerable pain threshold
- Short duration of symptoms
- Improvement by exercise program
- Improvement with brace treatment
- Minimal comorbidities present
- Strict long-term follow-up for dysplastic low-grade SL.

It is important to be aware of the risk of progressive slippage in skeletally immature patients with dysplastic low-grade SL who are managed conservatively. These patients should be followed closely until adulthood for the development of neurologic abnormalities.⁵¹

The authors prefer to perform conservative treatment based on Wiltse and Jackson's recommendations:

- For up to 25% subluxation in an asymptomatic child, observe with radiographs, initially every 4–6 months if under age 10, semiannually until age 15, then annually until the end of growth. No limitation of sports activities is recommended.
- A slip of 26–50% in an asymptomatic child, use same strategy as previous, with a warning regarding participation

in contact sports or sports with lumbar hyperextension (e.g. football and gymnastics).

- About <50% listhesis in a symptomatic child, initiate nonoperative treatment with bracing, anti-inflammatory medications, exercise with same recommendations as recommended by Wiltse et al.² If pain persists after 6 months, proceed to fusion.
- A slippage of >50% in a growing child, with or without symptoms should proceed to surgery.

Guidelines are described in the following sections for low- and high-grade SL treatment based on etiology (Table 108.4).

High-grade Slips

Children and adolescents with severe symptomatic SL do not respond favorably to nonoperative management, with the relief of symptoms in <10% of patients.⁵⁴ For this reason, surgical treatment is recommended in these patients. Based on the study by Harris et al., which describes the disease evolution and long-term follow-up for patients with severe SL, there is no evidence in support of prophylactic surgical treatment in asymptomatic patients however.³⁴

Surgical Management

A knowledge of the natural history of SL (i.e. slip advancement, progressive and incapacitating pain, or neurologic

deterioration) allows us to determine indications for surgery. The objectives of surgical treatment include the following:

- Prevention of further slip, achieved via stabilization of the olisthetic segment
- Correct associated deformities (i.e. lumbosacral kyphosis and rebalancing the spine)
- Relieve back or leg pain
- Reverse neurologic deficits.

Wild et al. outlined indications for spondylolysis and SL surgery, separating these into absolute and relative.⁵⁸ Absolute indications are defined as progressive neurological dysfunction, slip progression, or high-grade listhesis in pediatric patients, or significant lumbosacral kyphosis with associated gait abnormality. Relative surgical indications include minor or nonprogressive neurological dysfunction, radicular and claudication symptoms, or low back pain unresponsive to nonsurgical management.⁵⁸

The ideal surgical strategy continues to be controversial. Good clinical results have been described with multiple surgical techniques. These approaches include arthrodesis “in situ” with or without postural reduction, instrumented arthrodesis and reduction, and arthrodesis through combined anterior/posterior approach techniques. Selecting the surgical technique should be based upon careful analysis of the patient’s symptoms, clinical deformity and their neurological status. Considerations must also include the technical feasibility, surgeon’s preference and surgeon experience.

“In Situ” Arthrodesis

L4–S1 “in situ” posterolateral arthrodesis continues to be the preferred method of treatment for children and adolescents with severe SL. This procedure is commonly performed through a longitudinal or transverse central incision, or by the bilateral parasagittal approach described by Wiltse. In Wiltse’s approach, the transverse processes of L4, L5, and the sacral ala are widely exposed. When radicular compression is present, a bilateral L5 laminectomy with debridement of the pars interarticularis (Gill’s laminectomy) becomes necessary. An adequate arthrodesis surface preparation and appropriate corticocancellous bone graft are paramount to achieving a sufficient arthrodesis capable of withstanding the shearing forces at the level of the lumbosacral union.⁵⁹

This technique requires immobilization with a spica cast or a thoracolumbosacral orthosis with extension onto the thigh for a period of 8–12 weeks following surgery. In

the presence of deformity with partial mobility, it is possible to attempt a progressive postural reduction while molding the cast or the orthosis, by increasing the lumbosacral lordosis, thus correcting the shearing angle and improve overall sagittal balance. The use of transpedicular instrumentation allows for a reduction in duration of external immobilization during the postoperative period.

Different reports in the literature have shown that “in situ” arthrodesis can be achieved in 70–100% cases, with good results as to lumbar pain relief and neurological improvement in 75–100% of patients. A recent long-term outcome study concluded that the in situ group performed better in nearly all clinical parameters they assessed, and that fusion in situ be considered the method of choice for severe isthmic SL.⁶⁰

There is a risk for progression of the deformity during the postoperative period, which is usually correlated with insufficient immobilization, pseudoarthrosis or elongation of the fusion tissue mass. Pseudoarthrosis is usually asymptomatic, and in the majority of patients, the progression of the deformity is minimal and does not progress symptomatically. Transpedicular instrumentation reduces both the risk of pseudoarthrosis and the progression of the SL during the postoperative period.

In adolescents with severe lumbar pain and neurological symptoms associated to severe SL, the modified “in situ” arthrodesis described by Smith et al. could be implemented.⁶¹ This technique utilizes a structural fibular graft placed through a bony tunnel at the posterior aspect of vertebral bodies L5–S1, in addition to the posterolateral arthrodesis L4, L5–sacral ala, achieving a circumferential arthrodesis via the posterior approach alone. This technique has yielded promising clinical results with regard to pain relief and neurological improvement.

Arthrodesis with Reduction

Reduction of severe SL in children and adolescents is indicated if the shearing angle is $>45^\circ$, severe sagittal imbalance is present, or for patients at risk for developing pseudoarthrosis. Patients at risk for developing pseudoarthrosis are those who need a wide decompression at L5–S1, patients with severe lumbosacral union dysplasia, L5–S1 segment hypermobility, some anatomical variations (small transverse processes, sacral dysplasia, or spina bifida), and the presence of secondary changes at the lumbosacral union level (trapezoidal L5 or a round dome-shaped sacrum). Patients with these characteristics are candidates for fusion with reduction.⁶²

The main objectives of reduction are the following: reduce pelvic tilt, correct pelvic retroversion, reduce lumbosacral kyphosis, and reduce listhesis. The reduction of severe SL posits several possible advantages over the “in situ” arthrodesis technique alone. Reduction favors neural decompression, improves sagittal balance, and achieves a better aesthetic result. Restoring the lumbosacral alignment decreases the shearing forces at the level of the fusion, thus increasing the rates of fusion. To achieve reduction of a severe SL, the hips must be hyperextended in order to force pelvic anteversion and allow horizontalization of the sacrum.

There are many techniques described for severe SL reduction and fusion. These approaches include the following characteristics:

- Halofemoral traction with preoperative pelvic suspension
- Anteroposterior fusion and immobilization with a spica cast placed in hyperextension
- Posterior decompression and posterolateral arthrodesis followed by halofemoral traction
- Anterior arthrodesis in a second-stage reduction through external fixator and posterolateral instrumented arthrodesis
- Gradual intraoperative reduction with posterolateral instrumented arthrodesis
- Anterior release with partial reduction and anterior intersomatic fusion.

The use of instrumentation allows the patients to achieve faster mobilization and rehabilitation, and prevents the postoperative progression of SL. All strategies have proven to be efficient in reducing lumbosacral kyphosis, reducing sagittal translation, and obtaining a successful fusion. Ultimately, the surgeon must determine the optimal method for each case based on his/her personal preferences and experience after analyzing the potential risks associated with each technique with respect to the patient.

The reduction and instrumented arthrodesis is a much more challenging technical strategy, which requires a longer surgical time and has an associated increase in intraoperative blood loss compared to an “in situ” fusion.⁶³

The most serious complication following reduction of an SL is an iatrogenic neurological lesion. This has a direct relationship with the amount of reduction obtained. Isolated L5 radiculopathy is the most common complica-

tion, and is present in up to 30% of patients that underwent a reduction and fusion. During the reduction maneuver, up to 75% of the traction force over the root of L5 occurs in the second half of the reduction. Given the high neurological risk implied by a total SL reduction, it is recommended to perform a wide decompression, partial reduction, and posterolateral instrumented arthrodesis. This technique has proven to be useful and safe in children and adolescents who are not candidates for “in situ” fusion.⁶²

“In Situ” Arthrodesis versus Reduction

The indication for “in situ” fusion compared to fusion with reduction continues to be controversial. The literature is consistent in showing that the most relevant factor to achieve good clinical results is an adequate and solid fusion.

Several retrospective level III evidence reports showed no significant difference in the clinical results between “in situ” fusion and fusion with reduction.⁶⁴ However, the current recommendation is an “in-situ” fusion in those patients with a balanced pelvis (without pelvic retroversion), and fusion with reduction in patients with unbalanced pelvis (with pelvic retroversion). The classification below, posted by the Spine Deformity Study Group (SDSG), aids in describing the deformity, defining the prognosis, and helps guide the surgical treatment (Fig. 108.4).^{18,24,65,66}

Advantages of Reduction

- Re-establishes the sagittal balance
- Decreases pelvic tilt
- Corrects pelvic retroversion
- Transforms the shearing forces into compression forces
- Favors conditions for a solid fusion (8% nonunion)
- Allows for a neural decompression (corrections up to 50%)
- Lowers the risk of progression
- Allows for monosegmental fixations L5–S1
- Allows circumferential fusions adding anterior support through a posterior approach [PLIF (Posterior Lumbar Interbody Fusion) or TLIF (Transforaminal Lumbar Interbody Fusion)]
- Improves clinical results (90% good or excellent).

Disadvantages of Reduction

- Increases the risk of neurological lesions to 20–30% of cases

Slip grade	Sacro-pelvic balance and morphology	Spinal balance	Type
Low-grade	Nutcracker ($PI < 45^\circ$)	—	Type 1
	Normal pelvic incidence ($PI \geq 45^\circ$ and $< 60^\circ$)	—	Type 2
	High pelvic incidence ($PI \geq 60^\circ$)	—	Type 3
High-grade	Balanced (High SS/low PT)	—	Type 4
	Unbalanced (Low SS/high PT)	Balanced ($C7 \leq \text{hip axis}$)	Type 5
		Unbalanced ($C7 > \text{axis}$)	Type 6

Fig. 108.4: Spinal Deformity Study Group spondylolisthesis classification.⁶⁶
(PT: Pelvic incidence; SS: Sacral slope; PT: Pelvic tilt).

- In general, the neurological lesion is mild and transient, although it can be severe and permanent
- The most frequent lesion is the traction of the L5 root
- There is an increased risk of radicular lesion if the listhesis correction is $g > 50\%$
- It is important to perform a wide laminectomy in order to visualize both L5 roots during the listhesis reduction
- Surgery must always be performed using neurophysiologic monitoring.

Long-term Outcomes Studies

Better outcomes were found at 14-year follow-up after posterolateral fusion compared to direct repair of the pars defect.⁶⁷ Greater restriction of ROM (Range of Motion) in the adjacent disc and more rapid degenerative progression of the olisthetic segmental disc were also found, with a worse middle- and long-term clinical success for pars direct repair compared to posterolateral in situ noninstrumented fusion. This suggests a potential lack of benefit from a direct pars

repair. There are many studies describing different rates of successful repair with the various techniques; however, comparative studies have not been well documented. After a 6-month trial period of failed treatment, the safer and more predictable treatment strategy is to perform a posterolateral fusion. Exceptions to this recommendation include a pars defect cephalic to L5, multiple lesions, or low-grade reducible SL.⁶⁸⁻⁷¹

In a longitudinal study of 227 patients under 20 years of age, diagnosed of isthmic SL, Seitsalo et al. concluded the following¹⁴:

- The natural history of SL is associated with disc degeneration and spontaneous stabilization of the olisthetic segment.
- Fusion operations do not significantly accelerate degeneration of the adjacent segmental disc above the fusion at 14-year follow-up.
- There is no correlation between the number and degree of degenerated discs and subjective lower back pain in patients.

In a study of surgical outcomes in spine surgery stratified by diagnosis, Glassman prospectively studied 327 patients, showing that superior HRQOL (Health-Related Quality of Life) outcomes were seen after SL and scoliosis cases.⁷² Ostermann found that in 187 patients treated by posterolateral fusion, the only predictive factor for further slip was the amount of primary slip, and that one third of the surgically treated patients (average slip of 39%) suffered postoperative slip.⁷³ For comparison, in the conservative (nonsurgical) treatment group, the average slip was 16% and only 5% progressed.⁷³

Results from a study by Seitsalo involving 149 children with low-grade SL treated operatively or conservatively showed that while the operative group had greater preoperative pain and initial progression of the slip, those treated with fusion had better clinical outcome and less pain at follow-up evaluation than the conservative group.⁷⁴ None of the patients treated conservatively underwent surgery on follow-up, and those advised for surgery had the same outcome as the nonoperative control group.⁷⁴ In contrast to adult degenerative SL, nonunions (up to 35%) had comparable outcomes to patients who underwent fusion in a long-term follow-up. However, at short-term, patients with nonunion complained of significantly worse pain. Most nonunions were associated with mild slips. The progression of slipped vertebrae was higher (44%) in patients where the posterior elements have been resected as a decompression procedure, compared to 33%

in conservatively treated patients and 18% in surgically treated patients.⁷⁴

Additional decompression was a risk factor for nonunion. Patient's final surgical outcome did not differ with respect to pain or neurologic symptoms,⁴⁹ thus, no laminectomy has to be considered in surgical planning for low grade SL. Important to note is the lack of applicability to children, who have a greater potential for fusion. Seitsalo et al. showed that degenerative changes in the L4–L5 disc after fusion did not differ from the control group at a follow-up of 13.8 years, and no correlation between clinical symptoms and degree of degeneration was found.¹⁴ Lamberg reported similar results in a cohort of patients with nonunion (19% in this series).⁷⁵ Posterolateral in situ fusions yielded better fusion rates than posterior fusions, and 10% of patients had progression of the slip despite operation; however, clinical results were similar to the rest of the group.⁷⁵ Degenerative changes in the adjacent level were only 12% at 21 years, with no perceived clinical relevance.⁷⁵

After a prospective SRS (Scoliosis Research Society) database collection review including 25,432 pediatric cases, Fu et al. concluded that SL surgery contributed to 2.4% of all pediatric spinal operations. Of the 605 cases, 518 involved an instrumented fusion. They found no differences in surgical complication rates or neurologic deficits with instrumented and noninstrumented fusions, with a total complication rate of 10.4%. Complications were highly associated with reduction techniques, with a statistically significant difference.⁷⁶

Although instrumented fusion has shown better fusion rates, it is unclear if this holds true for children undergoing treatment for SL. Most surgeons prefer this method; there is no statistically significant difference in complication rate compared with in situ fusion, and there is relatively simplified postoperative management. Brace use is not indicated, whereas it is for 3 months in noninstrumented fusion.

Spondyloptosis Treatment

Spondyloptosis surgical treatment is one of the most challenging spine surgeries. Patients will present with severe lumbar pain, gait difficulties, and neurological symptoms. The circumferential “in situ” arthrodesis described by Smith and Bohlman is one alternative with relatively low risk for iatrogenic neurological lesion.⁶¹ The Gaines proce-

dures are often used, which consists of a partial vertebrectomy through an anterior approach of L5, followed by a vertebrectomy through a posterior approach of L5 (including a laminectomy and resection of pedicles), adding an instrumented reduction from L4–Sacrum. This is a very demanding technique that allows for realignment of the lumbosacral union and is associated with neurological lesions in up to 30% of the patients. A modified Gaines procedure was recently described, involving excision of the inferior half of the L5 vertebral body anteriorly, and posterior reduction and fusion.⁷⁷

SUMMARY

“In situ” fusion continues to be a very good option for the treatment of severe SL in children and adolescents.

The classification proposed by the SDSG, which differentiates severe SL into groups based upon pelvic balance, allows better description of the deformity, definition of the prognosis, and guidance for the treatment. In accordance with the latter, current evidence suggests that re-establishing the spinopelvic balance is critical to obtain a solid arthrodesis and good clinical results. The current recommendation for patients with balanced pelvis is the “in situ” fusion, and for patients with unbalanced pelvis, the partial reduction. The literature agrees that partial reduction is sufficient, and total reduction is often not necessary. The partial reduction allows for correction of pelvic tilt, lumbosacral kyphosis, restoration of spine–pelvis balance, by correcting the pelvic retroversion.

A solid fusion of the segment is key to achieving good clinical results. The partial reduction increases the rates of fusion as well as the clinical results in patients with unbalanced pelvis.

Prospective studies with better evidence level are warranted in order to accurately determine the role that the reduction plays on clinical results (Table 108.5).

CASE EXAMPLES

Case 1

The subject is a 15-year-old girl with 1 year history of lower back and buttock irradiating pain, tight hamstrings, and abnormal posture (A and B). Radiographs revealed unsuspected low-grade SL, with a high sacral slope of 60°, high pelvic incidence, low pelvic tilt, and high lumbar lordosis of 65°, classified as shear-type low-grade SL with dysplastic

Table 108.5: Mac-Thiong classification based on grade, dysplasia and spinopelvic balance.²⁴

<i>Grade of slip^a</i>	<i>Degree of dysplasia^b</i>	<i>Sagittal spinopelvic balance^b</i>	<i>Suggested treatment</i>
Low-grade (0, 1, or 2)	Low-dysplastic	Low PI/low SS (nutcracker type)	Parts repair (grade 0 or 1) versus in situ L5–S1 PLF ± instrumentation ± reduction ^c for grade 2
		High PI/high SS (shear type)	In situ L5–S1 PLF ± instrumentation ± reduction ^c for grade 2
	High-dysplastic	Low PI/low SS (nutcracker type)	In situ L5–S1 PLF and instrumentation ± reduction ^c for grade 2
		High PI/high SS (shear type)	In situ L5–S1 PLF and instrumentation ± L4 and pelvic fixation ± reduction ^c for grade 2
High-grade (3 or 4)	Low-dysplastic	High SS/low PT (balanced pelvis)	In situ L4–S1 PLF and instrumentation ± pelvic fixation ± partial reduction ^c
		Low SS/high PT (retroverted pelvis)	Partial reduction and L4–S1-pelvic instrumentation and PLF ± L5–S1 IF
	High-dysplastic	High SS/lot PT (balanced pelvis)	Partial reduction and L4–S1-pelvic instrumentation and PLF ± L5–S1 IF
		Low SS/high PT (retroverted pelvis)	Partial reduction and L4–S1-pelvic instrumentation and PLF and L5–S1 IF
Spondyloptosis	High-dysplastic		Circumferential fusion, instrumentation, with or without reduction

(PLF: Posterolateral fusion; IF: Interbody fusion using ALIF, TLIF, or PLIF technique; PL: Pelvic incidence; SS: Sacral slope; PT: Pelvic tilt).

^aAccording to the Meyerding classification.

^bDegree of dysplasia and spinopelvic balance as described in the “Pathogenesis” section of this chapter.

^cCorrection of lumbosacral kyphosis should be given strong consideration when slip angle is >10° and lumbosacral angle is >100°, or Spine Deformity Study Group lumbosacral angle is ≥15°.

posterior elements (C and D). Pain and progression are factors for consideration, and were indications for surgery. An in situ instrumented fusion was performed. The patient's pain resolved completely along with neurologic irritative signs, with complete return to functional activities. Postoperative radiographs and clinical appearance are shown (E to G).

Case 2

The subject is a 25-year-old woman with significant L5 radiculopathy and dysplastic pars. A posterior approach is used and the disc space is released through a TLIF-type approach. The deformity is then reduced and locked in place. The patient is flipped 180° in the same surgical session and an ALIF (Anterior Lumbar Interbody Fusion) is performed in addition to an S1 osteotomy.

Case 3

The patient is a 32-year-old male farmer with bilateral leg pain and back pain. A posterior approach is performed

with a Gill laminectomy as well as a TLIF at L5–S1. The L5 and S1 nerve roots are identified bilaterally; the listhesis is reduced; and a posterior spinal fusion is performed with local autograft.

Case 4

The subject is a 26-year-old female teacher with bilateral leg pain and hamstring tightness. A posterior approach is performed with a Gill laminectomy at L5. The bilateral L5 and S1 nerves identified and visualized and a TLIF is performed at L4–L5 and L5–S1. L5 is reduced onto S1 and a posterior spinal fusion is performed with local autograft. Fusion and stabilization to L4 is then performed in order to achieve solid fixation of proximal segments in high-grade slip. Interbody grafts are placed at L4–L5 and L5–S1 to restore anterior column support, help restore lumbar lordosis, and increase fusion surface area.

Case 1: A and B are clinical posterior and lateral views. C and D lateral and AP X-rays. E and F postoperative films in AP and lateral views, showing in situ posterolateral fusion with resection of posterior L5 arch. G shows clinical sagittal aspect, with normalization of lordosis.

Case 2: Postoperative lateral views.

Case 3: (A) Preoperative AP and lateral radiographic views. (B to D) Postoperative AP and lateral radiographic views.

Case 4: (A) AP and lateral radiography. (B) Lateral MRI views. (C and D) Postoperative AP and lateral radiographic views.

KEY POINTS IN EPIDEMIOLOGY

- The incidence of spondylolysis is 2–6% in the pediatric population.
- There are many racial or genetically related differences in the prevalence of SL.
- Most cases of SL will not progress after 20 years of age.
- The majority of patients with low-grade SL will remain asymptomatic or with minimal symptoms, and enjoy a quality of life similar to that of the normal population.
- About 90% of slips occur before the first clinical evaluation.
- Despite disease progression (referring to disc degeneration in the olisthetic segment), there is no correlation with increased occurrence of low back pain.

KEY POINTS IN PATHOGENESIS

In summary, the etiology of SL is related to each of the following, and characterized by the unique anatomical and functional characteristics of the lumbosacral segment:

- Hereditary
- Spinal balance
- Physical activities
- Dysplastic segment
- Slip angle or lumbosacral angles.

» Cervical Spine Injuries in Pediatric and Adolescent Athletes

» Thoracic/Lumbar Spine Injuries in Pediatric and Adolescent Athletes

INTRODUCTION

Understanding specific features of the immature spine enables a better understanding of pediatric spinal injuries. Vertical growth of the vertebral body occurs mostly at the chondroepiphyseal portions of the endplates. These areas enable circumferential expansion, while the posterior elements demonstrate longitudinal growth. An anterior growth plate exists at each neurocentral synchondrosis, and a posterior growth plate at the spinous process synchondrosis enables lengthening of the laminar and pedicular regions. Posterior element growth ceases at 5–8 years of age, after synchondroses closure, and anterior column growth continues until 17–18 years of age.

The term “ring apophysis” applies to the thickened periphery of the endplates and is the result of the ellipsoid enlargement of both the intervertebral disc and the primary ossification center. The central epiphysis thins, while the circumferential portions remain thick.¹

Skeletal maturity can be evaluated on lateral view plain radiographs by assessing the appearance of the secondary ossification center of the L3 vertebra (Fig. 109.1). The maturity stage of the vertebral body is classified as (1) the cartilaginous (“C”) stage, indicating that the secondary ossification center of the vertebral body is not visible on the radiograph; (2) the apophyseal (“A”) stage, indicating that the secondary ossification center of the vertebral body is visible on the radiograph and an ossified fragment is confirmed at the edge of the vertebral body; or (3) the

Fig. 109.1: Maturity stage of the vertebral body. Cartilaginous stage—no secondary ossification center of the vertebral body is visible (arrow). Apophyseal stage—the secondary ossification center of the vertebral body is visible (arrow), and an ossified fragment is evident at the edge of the vertebral body. Epiphyseal stage—the apophyseal ring is fused to the vertebral body (arrow). (y.o.: Years-old).

epiphyseal (“E”) stage, meaning that the apophyseal ring is fused to the vertebral body, suggesting vertebral maturation. Note however that the words “apophysis” and “epiphysis” are acknowledged as misnomers.^{2–4} Vertebral apophyseal ring fracture is a disease specific to the C- or A-stage immature spine. Furthermore, regarding isthmic spondylolisthesis that occurs subsequent to spondylolysis, slippage is more prevalent in individuals with a younger

skeletal age whose lumbar spine is immature, and it halted during the epiphyseal stage after the growth period when the vertebra had matured.²

CERVICAL SPINE INJURIES IN PEDIATRIC AND ADOLESCENT ATHLETES

Fractures of the Cervical Spine

Cervical spine injuries are potentially devastating and result in significant morbidity and mortality. The major mechanism of serious cervical injury is axial load—a large compressive force applied to the top of the head. This mechanism is more dangerous when the neck is in a slightly flexed position. The bimodal age distribution of patients sustaining cervical spine injuries shows a large peak at around 13–15 years and a smaller peak at around age of 5 years.^{5,6} Younger children are more likely to sustain cervical spine injuries caused by motor vehicle-related incidents, whereas older children and adolescents are more likely to incur cervical spine injuries during sports activities. The incidence of cervical spine injuries resulting from sports-related activities may be reduced by paying attention to physical conditioning and strengthening and managing regulations.

Burners and Stingers

Burners or stingers commonly occur in athletes participating in contact sports such as football, ice hockey, diving, and wrestling. The incidence of this transitory brachial plexus injury is approximately 30–50% over the course of a high school, college, or professional football player's career. Symptoms are severe burning or searing pain in the upper extremity after injury, and most injuries occur by one of three mechanisms: traction, compression, or hyperextension and compression. These injuries are clinically classified as neurapraxia, neurapraxia/axonotmesis, and neurotmesis according to their symptoms and the pattern of symptom resolution.

Most athletes can recover completely and return to sports activity following conservative treatment. Protective equipment and athlete education are required to decrease the occurrence of these injuries.

Cervical Spondylolysis

Cervical spondylolysis is rare; only 104 cases have been reported in the literature.⁷ Although no cases of cervical

Fig. 109.2: Three-dimensional reconstructed computed tomography scans of the cervical spine. Yellow circles indicate the bilateral location of cervical spondylolysis at C6.⁸

spondylolysis have been found in active athletes, no treatment strategies for athletes with cervical spondylolysis have been established. However, both cervical and lumbar spondylolysis could occur in athletes. Biomechanical results have shown that the increased disc stress and induced hypermobility in cervical kinematics observed in cervical spondylolysis may lead to cervical spinal cord injury when compared with an intact cervical spine (Fig. 109.2).⁸ Therefore, patients with cervical spondylolysis should abstain from any kind of contact sport.

THORACIC/LUMBAR SPINE INJURIES IN PEDIATRIC AND ADOLESCENT ATHLETES

Fractures of the Thoracic/Lumbar Spine

Pediatric spinal injuries constitute 1–10% of all spinal injuries, and the incidence of thoracic/lumbar injuries in children and adolescents varies between 5.4% and 34%.^{9–11} From a review of 89 pediatric patients with thoracic, lumbar, or sacral injuries by Dogan et al., the thoracic region was most affected (46%), followed by the lumbar (29.8%), thoracolumbar (19.2%), and sacral regions (5%).¹² Multi-level injuries are common and warrant imaging evaluation of the entire spinal column. In their review, the incidence of fracture caused by sports-related accidents was 21.3%, with 74% of all patients treated conservatively.

Many authors have advocated nonsurgical management consisting of bed rest or immobilization with a cast

or thoracolumbosacral orthosis for stable fractures in the pediatric population.^{13,14} The need for surgery depends on the type, level, and severity of the injury. Factors include persistent instability and significant compression fracture of the vertebral body (40% or more spinal canal compromise and/or 40% or more loss of spinal canal height), spinal kyphotic deformity of $>20^\circ$, vertebral dislocation, and spinal cord compression associated with progressive neurological symptoms.^{15,16}

Lumbar Disc Herniation

Lumbar disc herniation (LDH) is a common disorder in adults, but has a low prevalence in children and adolescents. In fact, pediatric patients constitute only 0.5–6.8% of all patients hospitalized for LDH.^{17–19} In a cohort study of 12,000 persons by Zitting et al., LDH leading to hospitalization first appeared around the age of 15 years, and the cumulative incidence increased sharply from the age of 20 in men, while increasing steadily in women.²⁰ By the age of 28 years, 9.5% of males and 4.2% of females were hospitalized for LDH, respectively.

There are several potential causes for pediatric LDH. A history of trauma before the onset of symptoms is a controversial predisposing factor. A review of the literature revealed that trauma including sports-related or self-reported injury is commonly considered the most likely cause of LDH because 30–60% of symptomatic pediatric patients have a traumatic history.^{21–26} A retrospective analysis of 165 patients identified a triggering event in 40% of LDH cases,²⁷ while another report showed that 82% of adolescent patients sustained trauma or were involved in intense sports activity.²⁸ On the contrary, the results of a retrospective analysis performed by Kumar et al. on 25 patients showed that only two patients (8%) had a history of significant trauma.²⁹ Regarding the association with athletic activities, magnetic resonance imaging (MRI) of asymptomatic adolescent elite tennis players showed that disc degeneration including LDH was present in 39.4% of all subjects.³⁰ Among elite swimmers, 68% had degenerative discs at various disc levels.³¹

Genetic factors are also considered predisposing factors. A family history of LDH was 67.8% in a retrospective analysis of 165 patients,²⁷ and Matsui et al. reported a familial predisposition for lumbar degenerative disc disease in their case-control study.³²

Diagnostic Imaging

Although the relationships between anatomic abnormalities of the lumbar spine detected by MRI, clinical history,

and patient outcome are controversial, MRI is an effective way of imaging LDH and neural structures. In addition, its noninvasive nature is suitable for pediatric patients.

Conservative Treatment

Conservative treatment for pediatric LDH patients consists of activities as tolerated, analgesic and nonsteroidal anti-inflammatory drugs, physical therapy, and limitation of athletic activities, which is similar to the treatment for adult LDH patients. A recent review of current treatments for LDH in children and adolescents by Dang et al. revealed that conservative treatment is not as effective in pediatric LDH patients as it is in adults.³³ They also provided several explanations for the disappointing results of conservative treatment in pediatric LDH patients. (1) Compared with adults, herniated nucleus pulposus in children has lower degeneration and is more hydrated, softer, and viscous,^{24,29,34} which means it might not dry up and be resorbed like a degenerated adult disc.³⁵ (2) Pediatric LDH is often associated with trauma where the annulus fibrosus could be severely ruptured.³⁶ (3) The apophyseal ring of the vertebral body in children and adolescents is not fully fused, hence severe trauma could rupture the apophyseal ring, forming a large implastic mass along with the herniated disc.³⁷ (4) Children and adolescents are active and less likely to comply to strict bed rest.

Surgical Treatment

Indications for surgical treatment include persistent symptoms despite conservative treatment, cauda equina syndrome, progressive neurological deficits, and associating spinal deformities.^{21,35,38,39} Several surgical procedures are available and include percutaneous endoscopic discectomy (PED), microendoscopic discectomy (MED), microsurgical discectomy or microdiscectomy (MD), open discectomy (OD) with/without laminotomy or laminectomy, and spinal fusion. To simplify the understanding of treatment options, these procedures are divided into two groups: “PED”, which includes PED and MED, and “OD” which includes the other procedures.

Percutaneous Endoscopic Discectomy

With the increasing use of endoscopic surgical techniques in spinal surgery, Mayer et al. applied endoscopy to the treatment of pediatric LDH.⁴⁰ Although they used the term “PED” in their case series, their procedure differed from

Figs. 109.3A to D: Herniated nucleus pulposus treatment. (A and B) Endoscopic control of nucleus pulposus removal. (C) Difference in wounds between percutaneous endoscopic discectomy (PED) and microendoscopic discectomy (MED). The patient underwent revision surgery with PED. (D) The circle shows the wound following PED.

conventional PED and is better considered as MED. In 1997, Foley and Smith described MED as a new percutaneous technique and in 2002 reported their first established results.⁴¹ Microendoscopic discectomy has since been adapted to the treatment of several diseases such as LDH, apophyseal ring fracture, and lumbar spinal canal stenosis. However, in 2010, Teli et al. reported a higher occurrence of severe complications (dural and root injuries, and recurrences) and surgical costs with MED compared with MD and OD.⁴²

Recently, PED was introduced as the least invasive procedure for LDH (Figs. 109.3A to D). Details of its surgical technique, outcome, and complications in 307 consecutive cases were first reported by Yeung et al. in 2002.⁴³ With PED, an 8-mm incision is sufficient for

inserting the percutaneous endoscope into the disc space for removal of herniated nucleus pulposus under local anesthesia. Although no long-term follow-up has been reported, several case series and case studies have been published.⁴⁴⁻⁴⁶ In the near future, PED is likely to be indicated for many pediatric LDH patients due to the procedure's low invasiveness.

Open Discectomy

Microdiscectomy consists of a 2- to 3-cm lumbar incision and minimal bone removal and is performed extensively in adults with low complication rates.⁴⁷ Cahill et al. reported the surgical results of a large single-institution series of MD in a pediatric population.⁴⁸ Their results showed that

MD is a safe option for pediatric patients. Postoperative infection, postoperative cerebral spinal fluid leak, and new postoperative neurological deficits each occurred in 1% of cases, with only 6% of patients needing revision surgery, and one patient requiring lumbar fusion.

Compared with PED, OD is associated with more sufficient decompression, but extensive dissection of soft tissues can also result in postoperative back pain. Since children and adolescents have greater nerve root tension than adults, extensive manipulation during discectomy should be avoided to avert nerve damage.⁴⁹ This limitation can be overcome by using MD; the small incision and the use of a microscope can reduce the risk of excessive nerve root manipulation and the likelihood of overlooking sequestered disc material.

Apophyseal Ring Fracture (Posterior Apophyseal Endplate Lesions)

A lesion of the lumbar posterior vertebral endplate, termed an apophyseal ring fracture, in children and adolescents causes symptoms similar to those of a herniated lumbar intervertebral disc. The end-plate lesion has been described as an apophysis, an ossified vertebral rim, an avulsion of the rim, or a fracture of the vertebral body.⁵⁰⁻⁵⁵ Apophyseal ring fractures likely result from mechanical stress applied to the apophyseal ring, which can lead to fracture of the vertebral growth plate.^{2,56,57} This fracture is more common in children and adolescents participating in sports.

Diagnostic Imaging

Diagnosis of posterior apophyseal ring fracture is made on plain radiography or computed tomography (CT) (Fig. 109.4). Although plain radiography showed an avulsed fragment in approximately 40% of cases,^{58,59} CT delineated the size, shape, and site of the fracture fragment clearly. In particular, multi-detector three-dimensional CT is useful for detecting such fragments; MRI had diagnostic utility in only 22% of cases.⁵⁹ Careful review of plain radiographs, supplemented by targeted CT, is necessary for the correct diagnosis and management of this entity.

Treatment

The principle of conservative treatment is similar to treatment for LDH and consists of bed rest, administration of analgesic and nonsteroidal anti-inflammatory drugs

Fig. 109.4: Reconstructed computed tomography scans showing the osseous fragments of the cross-sectional area at both the inferior and the superior L4 rim.

(NSAIDs), physical therapy, and limited physical activity with a lumbar or lumbosacral trunk brace.⁶⁰ Recently, Higashino et al. reported the long-term outcomes of conservative and surgical treatments in children and adolescents.⁶¹ Regardless of treatment, long-term outcomes were favorable. However, to facilitate rapid recovery and return to daily or physical activities, many authors have emphasized the need for operative treatment when conservative treatment fails. The purpose of surgical treatment is not only to decompress the neural structure but also to minimize surgical invasion and avoid related complications. Surgical treatment modalities involve removal of disc and bony fragments with or without spinal fusion.

Lumbar Spondylolysis

Lumbar spondylolysis is a defect of the pars interarticularis known to occur as a stress fracture in childhood or adolescence (Fig. 109.5). Since Wiltse et al. suggested in 1975 that spondylolysis begins as a fatigue fracture of the pars interarticularis,⁶² many studies describing the association of sports activities with spondylolysis have been published. The prevalence of lumbar spondylolysis is notably higher in athletes compared with the general population (6%);⁶³ the incidence of spondylolysis was reported to be 11% in female gymnasts⁶⁴ and 20.7% in college football players.⁶⁵ Among young athletes with low back pain, 47% had lumbar spondylolysis.⁶⁶

Biomechanically, high stress at the pars interarticularis is found in lumbar movements of extension and rotation,

Fig. 109.5: Lumbar spondylolysis. Typical oblique view of plain radiograph showing the Scottish dog's collar sign (arrow).

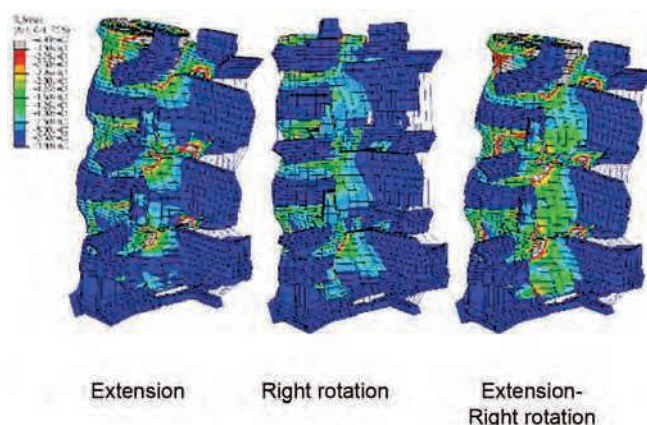

Fig. 109.6: von Mises stress distribution for different lumbar motions. Three lumbar motions showing the highest stresses during combined lumbar extension and right rotation compared with the simple extension/right rotation.

Fig. 109.7: Computed tomography scans of 12-year-old girl who did not comply with conservative treatment. The fracture line at the caudal-ventral aspect of the pars extending to the cranial-dorsal side 2 months after diagnosis.

which are considered the most likely motions to induce a stress fracture at the pars interarticularis (Fig. 109.6).⁶⁷ Furthermore, stress increases when the motion includes both extension and rotation. Two theories pertain to the initial event as a stress fracture. First, on the lumbar spine during extension, the inferior articular process of the cranial vertebra impacts the pars interarticularis of the caudal vertebra.^{62,68} Repetitive impacts of this nature can produce a stress or fatigue fracture of the pars interarticularis, which can be explained as direct compression by means of a “nutcracker” mechanism. Second, the pars interarticularis

breaks under tension through a traction mechanism.^{69,70} Observation of clinical cases and the results of a biomechanical study revealed that spondylolysis as a stress fracture is initiated from the ventral aspect due to the higher concentration of stress at the site during lumbar motion (Fig. 109.7).⁷¹ Thus, there is no doubt that spondylolysis is a stress fracture. However, many aspects regarding the etiology of spondylolysis remain to be clarified.

Clinical Presentation

When adolescent athletes have low back pain that is aggravated by athletic movement, lumbar spondylolysis should be considered. In particular, if low back pain is induced by lumbar extension and/or rotation, Kemp's test will be positive and pinpoint tenderness will be observed on the spinous process of the affected vertebra, making lumbar spondylolysis the most likely culprit. Sometimes, low back pain is accompanied by radiculopathy, which is thought to be induced by extraosseous hematoma or edema at the site of spondylolysis.⁷²

Diagnostic Imaging

It has been noted that bony union of the pars defect can be achieved in children if they refrain their sports activities and wear a trunk brace. To attain bony union, early diagnosis is extremely important to promote bony healing of the pars, and the stage of the defects at the first presentation largely affects prognosis following conservative treatment (Fig. 109.8).⁷³ Furthermore, high-signal change in the

Fig. 109.8: Representative computed tomography (CT) scans of pars defects in each stage. On the basis of CT findings, the defect is classified into three stages: early, progressive, and terminal.⁷³

pedicle adjacent to the pars defect on T2/short TI inversion recovery—MRI has been shown to be an indicator of early-stage spondylolysis (Fig. 109.9).^{74,75} Therefore, axial slices through the pedicle combined with standard images around the disc space should be obtained by screening MRI to avoid missing early-stage spondylolysis in children and adolescents.

Conservative Treatment

In pediatric patients with lumbar spondylolysis, the ideal goal is to achieve bony healing conservatively. For patients with early-stage or progressive-stage spondylolysis, the ideal goal is to attain bony union. As lumbar extension and rotation are risk factors, restricting trunk extension and rotation is considered an optimal approach for achieving bony union. Therefore, conservative treatment involves wearing a molded plastic hard thoracolumbosacral orthosis and refraining from all athletic activities.^{76,77} In most cases, 3–6 months are required for bony healing (Table 109.1). However, for patients with terminal-stage spondylolysis, achieving bony union with conservative treatment is impossible, as conservative treatment consists of pain management to support a return to athletic activities. Sometimes, inflammation is present at the pars defects and adjacent facet joints, which may cause low back pain (Fig. 109.10).⁷⁸ If the skeletal age of the patient is immature (cartilaginous or apophyseal stage), subsequent slippage (isthmic spondylolisthesis) can develop (*see* Fig. 109.1).² Careful management of patient, especially if female, is therefore required.⁷⁹

Fig. 109.9: Signal change defined as high-signal change (HSC) on fat saturation sequences. HSC is visible in the bilateral pedicles at L5.

Table 109.1: Union rate and duration to achieve bony healing according to the CT and MRI classification.⁷⁶

Parameter	CT stage			
	Progressive			
	HSP		No HSP	
	Early	on MRI	on MRI	Terminal
No. of defect	33	11	11	8
Union	31	7	3	0
Union rate (%)	94	64	27	0
Duration until union (mos)	3.2	5.4	5.7	NA

(HSP: High signal change at the adjacent pedicle; NA: Not applicable; CT: Computed tomography; MRI: Magnetic resonance imaging).

Surgical Treatment

Surgical treatment should be indicated only for patients with a mature spine and terminal-stage spondylolysis causing persistent and severe low back pain and/or leg pain. For pediatric patients with an immature spine, surgery is not recommended. To treat low back pain caused by painful spondylolysis, direct repair of the pars defects is performed. Several techniques have been reported, including screw placement into the defects (Buck's technique),^{80,81} the wiring method,⁸² and the pedicle screw and hook method.⁸³ In some patients, radiculopathy can be combined with lumbar spondylolysis. The main lesion compressing the nerve root is usually at the proximal portion of the spondylolysis and is known as the ragged

Fig. 109.10: Computed tomography showing terminal-stage bilateral L5 spondylolysis. Short T1 inversion recovery—magnetic resonance imaging of a 14-year-old male soccer player clearly indicating effusion at the defect and both adjoining facet joints.

edge of the lysis. Therefore, nerve root impingement can be decompressed with an endoscope to treat this radiculopathy.⁸⁴

Spondylolisthesis

Spondylolisthesis is subdivided into five subtypes: isthmic, degenerative, dysplastic, congenital, and traumatic. The isthmic type is caused by a defect in the pars interarticularis, called spondylolysis, pars defect, or pars fracture, and, along with the degenerative type, is one of the two most common forms of spondylolisthesis. Isthmic spondylolisthesis is thought to occur in children and adolescents based on epiphyseal separation, which is due to a physeal stress fracture of the vertebral body.⁸⁵ Therefore, slippage progression in isthmic spondylolisthesis usually occurs during the growth spurt and is minimal after skeletal maturity.² On the other hand, it is well known that the pathogenesis of degenerative spondylolisthesis is associated with disc degeneration, followed by facet laxity and ligamentum flavum hypertrophy, which results in spinal canal stenosis. Therefore, degenerative spondylolisthesis is common in those aged over 40 years. As mentioned above, isthmic spondylolisthesis involves subsequent slippage of spondylolysis. Slippage is more prevalent in individuals with a younger skeletal age whose spine is immature, and slippage is halted when the growth period is over and the vertebrae have matured.² Therefore, only isthmic spondylolisthesis is focused on in this chapter.

Clinical Presentation

In isthmic spondylolisthesis, low back pain is a common initial symptom. Some patients have radiculopathy in the lower extremities caused by fibrocartilaginous proliferation around the pars defect. This radiculopathy affects the exiting nerve root associated with the cephalad vertebra of the involved spinal segment. Most cases of L5 spondylolysis involve the L5 nerve root. Thus, typical symptoms of isthmic spondylolisthesis are low back pain due to spinal instability and radiating leg pain due to the compressed exiting nerve root. Furthermore, in isthmic spondylolisthesis, pseudodisc bulging is easily identified.

Surgical Treatment

Most patients who develop isthmic spondylolisthesis are asymptomatic. In adolescents with symptomatic isthmic spondylolisthesis, pain relief is achieved in approximately 70% of cases after conservative therapy,⁸⁶ which includes administration of NSAIDs, selective nerve blocks, injections into the pars defect, brace therapy, restriction of sports activities, and occasionally bed rest. Moreover, indications for surgical treatment in patients with an immature spine must be carefully considered after taking into account skeletal age, severity of symptoms, and degree and progression of instability.

Low-grade Spondylolisthesis (Grade I or II)

Noninstrumented fusion: A retrospective study with a long-term follow-up (mean: 19.7 years) of uninstrumented posterolateral spinal arthrodesis in 49 adolescents with grade I or II lumbar isthmic spondylolisthesis showed an outcome of good spinal fusion in 43 (87.7%) patients who attained solid fusion and pseudarthrosis in six patients (12.3%).⁸⁷ Satisfactory results were obtained in 94% of patients, and these outcomes were closely associated with the rate of successful fusion.

Instrumented fusion: Numerous operative procedures have been described for isthmic spondylolisthesis including posterolateral fusion (PLF) with or without decompression, possibly with spinal instrumentation and possibly including anterior lumbar interbody fusion, posterior lumbar interbody fusion, transforaminal lumbar interbody fusion, and circumferential anterior and posterior fusion. However, for patients with an immature spine, indication of these surgical treatments is controversial because the effect of spinal growth on the outcome of

lumbosacral spinal fusion remains unclear, although remodeling of the fusion area has been noted to decrease slippage in younger children.⁸⁸ A recent long-term follow-up study following surgical treatment for isthmic spondylolisthesis in a significant number of adolescents and children who underwent surgery before the pubertal growth spurt was reported by Jalanko et al.⁸⁹ Their results showed satisfactory outcomes in both groups, and patients who underwent surgery during or before the pubertal growth spurt had a statistically better outcome in low back pain scores compared with adolescents at the final follow-up.

High-grade Spondylolisthesis (Grades III, IV, or V)

High-grade isthmic spondylolisthesis comprises a distinct minority of all patients with spondylolisthesis, but treatment of these high-grades of spondylolisthesis can be complex and difficult, and the optimal treatment of this pathology remains controversial. The clinical indications for surgical treatment of high-grade spondylolisthesis include continued pain despite conservative treatments, spinal deformity progression, and neurological symptoms. Most patients with high-grade spondylolisthesis or spondyloptosis—which is complete subluxation of the cephalad vertebra from the lower vertebra classified as a grade V spondylolisthesis—become symptomatic during adolescence. A recent literature review on surgical treatment for high-grade spondylolisthesis in the pediatric population concluded that it was impossible to formulate clear guidelines for the treatment of high-grade spondylolisthesis based on the best evidence available in the published literature because of the paucity of high-level studies available on this topic.⁹⁰ Many studies focusing on a reduction in high-grade spondylolisthesis have been performed. An L5 vertebrectomy and reduction of L4 onto S1 as surgical treatment for fixed spondyloptosis was described by Gains.⁹¹ The most widespread reduction method for high-grade spondylolisthesis is posterior decompression, reduction, and fusion with placement of segmental spinal instrumentation.⁹² Another option for the treatment of adolescent spondyloptosis is the use of an external fixation device.⁹³

INTRODUCTION

Management of spinal deformity includes recognition and treatment of scoliotic, kyphotic, and spondylolisthetic conditions. Historically, treatment has focused upon scoliosis correction and prevention of scoliotic curve progression; however, recent data has demonstrated the impact that sagittal plane deformities and global spinal alignment have in the generation of pain and disability. Consequently, increased emphasis has been placed upon restoring physiologic lumbar lordosis (LL), thoracic kyphosis (TK), and the C7 plumb-line [sagittal vertical axis (SVA)]. The spinopelvic relationship has been less frequently evaluated when treating spinal deformities. The position of the pelvis plays a critical role in maintaining upright, sitting, and standing postures by acting as an intercalary unit between the spine and the lower extremities.^{1,2} Failure to account for pelvic alignment when treating spinal deformity increases the risk of spinal malalignment, and subsequent long-term decompensation, resulting in treatment failure. Furthermore, a paradigm shift is emerging in which the spine is being studied as a whole, with alignment relationships extending from the pelvis to the cervical spine. Recent studies have shown that regional spinal parameters are not independent of one another and have a large impact on other areas of the spine, including the pelvis.³ This chapter will review the spinopelvic parameters needed to evaluate adult spinal deformities and the implications these measures have for treatment.

SACROPELVIC MORPHOLOGY

There has been increasing recognition of the important role of the pelvis in spinal alignment.⁴⁻¹⁸ The most commonly assessed radiographic measures of sagittal spinopelvic alignment include pelvic incidence (PI), pelvic tilt (PT), and sacral slope (SS). Pelvic incidence is defined as the angle subtended by a line drawn between the center of the femoral head and the sacral endplate and a line drawn perpendicular to the center of the sacral endplate (Fig. 110.1).^{12,19} Pelvic incidence is a morphologic parameter that remains consistent during the patient's lifetime, with slight changes occurring during prepubertal development. Following puberty, PI is generally considered to be a fixed, morphologic parameter, reflecting the relationship of the sacrum to the pelvis. Pelvic tilt is defined as the angle subtended by a line drawn from the midpoint of the sacral endplate to the center of the bicoxofemoral axis and a vertical plumb line extended from the bicoxofemoral axis (Fig. 110.2).¹⁹ Sacral slope is defined as the angle subtended by a line drawn along the endplate of the sacrum and a horizontal reference line extended from the posterior superior corner of S1 (Fig. 110.3).¹⁹ It has been previously established that these parameters are correlated and are predictive of the ideal LL (large PI requires a large LL),^{5,12} thus creating a spinopelvic chain of correlation in adult volunteers.^{16,20} A mathematical relationship exists such that the PI is the sum of the PT and SS ($PI = PT + SS$).^{12,19} As the PT increases, the SS decreases due to the sacrum assuming a more

Fig. 110.1: Diagram showing the measurements of pelvic incidence (PI).

Fig. 110.3: Diagram showing the measurements of sacral slope (SS). (HRL: Horizontal line).

vertical position about the femoral head axis (pelvic retroversion). Pelvic retroversion is a compensatory mechanism used to sagittally rebalance the spine and maintain upright posture in cases of sagittal spinal misalignment (SSM) (e.g. compensate for decreased LL). Normal gait requires forward flexion of the pelvis. If the pelvis is retroverted (high PT) during gait, the hip joint is externally rotated. Therefore, the knee joints internally rotate to compensate for the abnormal hip position.^{21,22}

Just as PT and PI must be considered preoperatively to achieve global spinal alignment in the sagittal plane, pelvic obliquity or coronal plane pelvic deformity and associated etiology should be considered in the coronal plane correction strategy. Pelvic obliquity is quantified by measuring the angle formed between a horizontal reference line and a line drawn between the two inferior points of the sacral ala on an anteroposterior X-ray (Fig. 110.4).

Pelvic obliquity due to leg-length discrepancy from congenital or acquired conditions (e.g. hip or knee osteoarthritis, prior arthroplasty) or from sacropelvic deformity may produce a compensatory lumbar curve to balance the spine. Correction of this lumbar curve without correction of the primary driver of the pelvic obliquity may lead to coronal decompensation. In other cases, the pelvic obliquity may be secondary (attempting to compensate) to the spinal scoliotic curve, and curve-correction strategies must be of sufficient magnitude to allow the pelvis to relax in the coronal plane. Surgical planning with regard to pelvic obliquity is discussed further.

■ SPINOPELVIC ALIGNMENT

Concept of Cone of Economy

The ability to effectively maintain a standing upright posture is fundamental to normal human function. Spinal deformities often impair the ability to maintain upright posture. Recent studies of patients with spinal deformity

Fig. 110.4: Method for measuring pelvic obliquity.

have demonstrated that global spinal malalignment is a strong predictor of disability.^{10,23-25} Despite the importance of posture and balance to human function, the defining and impacting factors remain incompletely understood.¹⁶

Dubousset introduced the concept of a “cone of economy” to describe the fundamentals of optimal standing balance and posture.²⁶ This concept is based on a cone, centered at the feet of a standing individual, which projects upward and outward. This cone defines the range of standing postures for which the body can remain balanced with minimal effort and free from external support. In essence, the cone is defined by the range of sway of the center of mass, relative to the feet, that can be readily accommodated by the structural elements and musculature of the standing individual. As the body moves toward the periphery of this cone, additional effort and energy expenditure are necessary to maintain balance. Beyond the perimeter of the cone, external support, such as a cane, crutch, or walker, may be necessary to prevent the individual from falling.

The substantially greater energy that is required to maintain unsupported standing posture that approaches the periphery of the “cone of economy” or beyond can produce fatigue, pain, and disability.²⁶ Several radiographic measures have been defined for the assessment of spinal alignment in addition to the pelvic parameters discussed earlier; including coronal and sagittal measures.

Assessment of Sagittal Alignment

Multiple parameters are used to describe sagittal alignment (SA). The most common measure of global SA is the SVA, which is assessed on lateral 36-inch standing radiographs. Sagittal vertical axis is defined as the horizontal offset between the C7PL and the posterior superior aspect of the S1 vertebral body (Fig. 110.5A). Positive and negative values of SVA reflect cases in which the C7PL falls anterior or posterior to the posterior superior corner of the S1 vertebral body, respectively (Fig. 110.5A). The T1 spinopelvic inclination²⁷ (T1SPI) and the T9 spinopelvic

Figs. 110.5A and B: Measurement parameters for spinal sagittal alignment (A). The sagittal vertebral axis is measured as the distance from the posterior superior corner of the sacrum to a vertical plumb line dropped from the C7 centroid shown as +X (B). Spinopelvic inclination (SPI) is a global angular measurement of sagittal alignment. The SPI is the angle formed by a line from the femoral heads to the T1 or T9 centroid and the vertical plumb line. Because this is an angle rather than a length measurement, it is not subject to magnification variability in X-ray.

inclination (T9SPI) are alternative measures of SA. These measures are angles between the vertical plumb line extended from the bicoxofemoral axis and lines drawn from the vertebral body center of T1 or T9 to the center of the bicoxofemoral axis (Fig. 110.5B). As the T1 and T9 inclination are angles rather than measured lines, they are not prone to radiographic magnification issues. Sagittal alignment is also assessed through regional measures of thoracic and lumbar alignment, including Cobb angles of TK (T2–T12, T2–T5, and T5–T12; Fig. 110.6A), thoracolumbar kyphosis (TLK; T10–L2), and LL (T12–S1; Fig. 110.6B).

Assessment of Coronal Alignment

Coronal alignment (CA) is assessed using 36-inch standing radiographs. The CA is the horizontal distance between the C7 plumb line (C7PL)—a vertical line dropped from the middle of the C7 vertebral body—parallel to the lateral edge of the film, and the central sacral vertical line (CSVL), which is the vertical line in a coronal radiograph that passes through the center of the sacrum (Fig. 110.7). A CA of zero is designated as “neutral”. Malalignments to the left or right of the neutral line are designated as negative or positive distances, respectively.

Figs. 110.6A and B: (A) Diagram showing the method for measuring thoracic kyphosis. Typically, thoracic kyphosis is measured from T5 to T12 as, often, the T2 endplate is difficult to visualize. (B) Diagram showing the method for measuring lumbar lordosis. Lumbar lordosis is generally measured from T12 to S1 ($-X$) and thoracolumbar alignment from T10 to L2 ($+X$).

Normal Values of Spinopelvic Alignment

The normal value of CA is zero, as the spine should be vertically straight in the frontal plane; therefore, the C7 should be aligned centrally over the sacrum. The normative values for sagittal spinopelvic parameters are less concisely defined, and often are dependent on age.^{5,12,16,28-31} With increasing age, SVA, T1SPI, T9SPI, TK, and PT tend to increase, whereas LL tends to decrease with age.^{5,12,16,28,30,31} Normative spinopelvic values have been reported in an adult volunteer population by age groups and are listed in Table 110.1.³

GLOBAL SPINOPELVIC ALIGNMENT RELATIONSHIPS

The spinal regions (pelvis, lumbar, thoracic, and cervical) are not independent of one another and multiple significant correlations have been found between them,³

consistent with the described necessity to preserve a neutral SA as reported by Kuntz et al.³² A recent study³ investigated all spinal parameters in an asymptomatic volunteer population with a mean age of 45 (range, 20–77). Following an extensive analysis, the authors found that PI correlates with LL, LL correlates with TK, and TK correlates with CL (Fig. 110.8).³ Thus, an increase in PI correlates with an increase in LL, which correlates with an increase in TK, which then correlates with an increase in CL.³ However, there was a lack of correlation found between PI and TK, making the chain of correlation from the pelvis to the cervical spine more complicated. The current view is that LL is proportional to PI and TK because PI is a fixed parameter and TK has little flexibility. Subjects with a small PI or small TK had smaller LL than subjects with small PI and large TK. This demonstrates that TK is not a result of LL, but rather, LL is a result of TK and PI. As mentioned earlier, CL was correlated with TK showing that, as TK

Fig. 110.7: The distance between the C7 plumb line (C7PL) and the central sacral vertical line (CSVL) defines the amount of coronal plane decompensation in centimeters (termed $-X$ in this picture).

increases, CL also increases. However, this change in CL is not large enough to maintain the head over the pelvis, but it does provide adequate maintenance of horizontal gaze. In addition to the correlations between CL and TK, CL was also found to correlate with the SVA, PT (Fig. 110.9), and T1 slope.³ Subjects that had a positive SVA demonstrated an increase in cervical lordosis, regardless of whether their SVA was within the normal range of values. This cervical adaptation to the sagittal global alignment is a compensatory mechanism in order to maintain a horizontal gaze as mentioned earlier. Therefore, cervical lordosis can be considered, similar to TK and LL, as an adaptive spinal mechanism to maintain global alignment. When LL and TK are adapted to the patient's pelvic incidence, the amount of cervical lordosis will be proportional to the other curves. However, when the patient has an anterior malalignment of the spine (from a reduction in LL and/or an increase in TK), an increase in cervical lordosis is a compensatory mechanism. Conversely, if a primary cervical deformity exists, changes in the lumbar spine and pelvis will attempt to compensate.

■ IMPORTANCE OF SPINOPELVIC PARAMETERS IN SURGICAL PLANNING

Health-related quality of life (HRQOL) scores following surgery for adult spinal deformity are strongly correlated with the achievement of sagittal and coronal spinal alignment.^{33,34} Traditionally, SVA and C7-CSVL offset have been used to assess sagittal and coronal alignments,

Table 110.1: Mean sagittal parameters among the volunteers stratified by age group.³

	20–39 years		40–59 years		> 60 years		P value

P values refer to ANOVA comparison between groups.

Fig. 110.8: Chain of correlation between PI and regional sagittal parameters with the corresponding Pearson coefficient r values. A large PI requires a large lumbar lordosis. An increase of lumbar lordosis is correlated with an increased thoracic kyphosis, which is correlated with an increased cervical lordosis.

Fig. 110.9: Correlation between pelvic tilt and lumbar/cervical lordosis. A loss of lumbar lordosis is correlated with a pelvic retroversion acting as compensatory mechanisms. Pelvic retroversion is also correlated with an increased cervical lordosis.

respectively, with the goal of corrective surgery to achieve $SVA < 4$ cm and $CA < 4$ cm. Recently, however, Lafage et al. reported that T1SPI more accurately correlated with HRQOL scores than SVA.¹⁰ The authors also reported that increased PT values were reflective of pelvic retroversion and correlated with worsening HRQOL scores.¹⁰ Accordingly, Schwab et al. used normative data and postoperative HRQOL measures to evaluate the maximal amount of tolerable sagittal and coronal spinal malalignment in order to provide radiographic alignment guidelines for spinal reconstructive procedures.³⁵ Based on the evaluated data, the authors reported that the goal of spinal realignment procedures should be: $SVA < 50$ mm, $T1SPI < 0^\circ$, and $PT < 20^\circ$.³⁵ Additionally, the authors emphasized evaluating the pre- and postoperative relationships between LL and PI as an assessment of spinopelvic harmony. The ideal

relationship that was consistent with normative data and correlated with good postoperative HRQOL scores was $LL = PI \pm 9^\circ$.³⁵

In an attempt to optimize postoperative SA, several authors have proposed mathematical formulas to aid surgical planning. These formulas vary in the amount of complexity, as some formulas simply provide a target postoperative LL:TK relationship, whereas others estimate the degree of osteotomy resection needed to restore SA. Ondra et al. used a trigonometric methods to calculate the angle of correction needed to achieve neutral alignment for pedicle subtraction osteotomy (PSO) procedures.³⁶ One shortcoming of this method, however, is that the contribution of the pelvis to SA is neglected. As indicated earlier, the amount of LL required to restore physiologic SA is not the same for every spine, but instead, varies with PI. Additionally, patients increase PT to compensate for global spinal malalignment. This compensatory increase in PT results in increased energy expenditure contributing to greater disability.¹⁰ For patients that have SSM and increased PT, normalization of PT requires greater angular correction³⁷ than predicted by Ondra's technique. This shortcoming must be recognized, as patients with severe SSM are at risk of under-correction if the magnitude of the spinopelvic deformity is not recognized and a single level PSO is carried out.³⁸ If greater sagittal correction is needed, a variety of methods can be employed to supplement the correction generated by the PSO, including adjacent-level interbody grafting combined with Ponte-type osteotomy. Another option may be to combine two types of three column osteotomies in order to achieve optimal coronal and SA.

Another important consideration when planning spinal reconstructive procedures is that the spinal segments that are not incorporated into the fusion may change alignment, which, in turn, can significantly impact the achievement of optimal postoperative spinal alignment. Lafage et al. reported on the negative impact that an increased TK following lumbar PSO has upon postoperative SA.³⁹ The patients in this study developed a reciprocal increase of 13° of TK within the nonfused thoracic spine after lumbar PSO.³⁹ This increase in TK resulted in poor postoperative spinal alignment in 18/34 study patients.³⁹ This phenomenon is more common in patients with higher PI, greater preoperative SSM, and older age, with an average age of 59 years old.³⁹

Currently, the amount of reciprocal thoracic change cannot completely be predicted preoperatively. Prediction of such unfavorable thoracic reciprocal changes is difficult for the following two reasons: (1) the preoperative assessment of TK may be inaccurate due to the anterior malalignment, and (2) patients with an increased sagittal vertical axis tend to reduce their TK by muscular contracture in order to maintain the head over the pelvis. However, one can look to the patient's morphology (in addition to the three parameters discussed earlier: high PI, large SSM, and older age), to attempt a prediction. Roussouly and Nnadi⁴⁰ describe a classification system (types 1–4) of patients based on their SA morphologic characteristics. In this system, patients are classified based on their length ratios of the thoracic kyphotic curvature to lumbar lordotic curvature with type 1 through type 4 being 80:20, 60:40, 50:50, and 20:80 respectively.⁴⁰ Thus, patients that are classified as type 3 are well balanced, whereas patients classified as type 4 have a large PI, long LL, and a short and pronounced TK (ratio 20:80). Type 4 patients may be at a higher risk of postoperative unfavorable reciprocal thoracic changes than type 3 patients.

When deciding on the location of an osteotomy, current thinking places the greatest importance on the location of the osteotomy, which impacts the amount of translational correction that can be gained. The lower a 30° osteotomy is placed in the lumbar spine, the more impact it has on plumb-line correction. Larger angular corrections are needed in superior locations in the spine to affect the same translational shift in the plumb line compared to osteotomies located in the caudal locations of the spine.

However, recent work by Lafage et al. has shown that the osteotomy location may not be as critical.⁴¹ Based on the level of the osteotomy, there was no difference in the

focal correction and no correlation with SVA correction.⁴¹ Preoperative PT and unfavorable thoracic reciprocal changes must be accounted for in calculating the amount and location of correction angle needed for optimal alignment. More caudal osteotomies in the lumbar spine were significantly correlated with greater PT reductions and the degree of osteotomy was significantly correlated with changes in TK.⁴¹ The ideal alignment accounts for a relaxed thoracic spine and a normal PT as well as optimal SVA.

Patients with elevated SVA and low PT (lack of pelvic compensation for a high SVA) represent a distinct subgroup of patients in whom attempted operative correction is subject to greater risk of postoperative failure. This pattern may be seen in (1) patients with pre-existing hip flexion contracture, (2) degenerative flatback patients with primary extensor muscle pathology,⁴² (3) globally decompensated patients with secondary extensor muscle weakness, and (4) patients leaning forward to compensate for severe lumbar stenosis. All patients in whom corrective surgery is being considered should undergo evaluation to rule out hip flexion contracture. Typically, the Thomas test is performed with the patient supine, with the leg bent and pressed against the lower torso, while monitoring the contralateral leg for signs of knee flexion. Patients with mild extensor muscle weakness may be referred for hip-extensor-strengthening physical therapy preoperatively.

Lee et al. advocated the separation of degenerative flatback patients into those that are able to maintain PT when ambulating and those that tilt forward and are unable to maintain their PT when walking.⁴² Gait studies have demonstrated significant abnormalities in patients with postoperative sagittal malalignment, and this is likely related to the fact that patients incline their pelvis forward when walking. If pelvic retroversion is being used to maintain standing balance, this compensatory mechanism will be maintained during walking, thus placing the pelvis in a nonphysiologic position. The ability to maintain this pelvis retroversion while walking demonstrates adequate pelvic extensor muscle strength but comes at the cost of increased energy expenditure, hip external rotation, and knee internal rotation in gait analysis studies.²²

Given the importance of achieving spinal pelvic harmony and the frequent occurrence of unfavorable reciprocal changes after corrective surgery, several formulas for prediction of ideal postoperative SVA have been developed.^{15,43,44} The predictive accuracy of these formulas has recently been analyzed in a large PSO database.⁴⁵

The most accurate formulas include PI and PT as well regional spinal curvatures including TK and LL in the Lafage formula (Table 110.2).^{15,36,45, 46-49}

Pelvic Obliquity and Scoliosis Correction

As mentioned earlier, pelvic obliquity may be a result of a leg-length discrepancy from congenital or acquired conditions (e.g. hip or knee osteoarthritis, prior arthroplasty) or from sacropelvic deformity, which may produce a compensatory lumbar curve to balance the spine. All patients should be evaluated clinically and radiographically for a leg-length discrepancy and, if identified, re-evaluated after fitting with a shoe lift to assess how the spine and pelvis respond to correction of the leg-length discrepancy both clinically and radiographically. This can be done by obtaining a standing anteroposterior pelvic X-ray with subsequent lower extremity scanograms if the pelvis is found to be uneven. Patients with a flexible curve secondary to a pelvic obliquity due to a leg-length discrepancy may respond well to the addition of a shoe lift only or surgical treatment of the leg-length discrepancy. If the spinal curve is rigid, it will not correct after the addition of a shoe lift. In this case, there are two options: (1) to correct the curve perpendicular to the oblique pelvis and ignore the pelvic obliquity and (2) to correct the spine to a level pelvis if leg-length correction is planned (e.g. with a future hip replacement) or the patient tolerates a shoe lift (Fig. 110.10).

Prediction of ideal curve correction in the setting of double major curves and curve patterns with lumbosacral fractional curves can be quite challenging. Careful study of the preoperative side of malalignment will determine the magnitude of the curve corrections possible while maintaining standing global coronal balance. Often, the fractional curve may allow rebalancing of the spine via small angular coronal corrections at the lumbar sacral junction. Comparison of preoperative standing and prone films may assist the surgeon in estimating the anticipated difference in alignment likely to be seen on the operative table and, therefore, the likely magnitude of optimal curve correction. Preoperative bending films will also assist the surgeon in determining how much correction may occur if a curve is not included in the fusion. Intraoperative full-cassette films should be obtained and interpreted with an understanding of the patient's baseline pelvic malalignment. These are obtained by placing the long film plate on a stool underneath a radiolucent table for anterior-posterior imaging and by placing the long cassette on a film holder lateral to the patient. The global sagittal plane is more accurately assessed than the global coronal plane, in general, because leg-length discrepancies that mainly impact the coronal plane are not easily assessed until the patient stands in the early postoperative period. Thus, as it is often difficult to predict how the patients with complex curve patterns and pelvic obliquity will correct when standing, early

Fig. 110.10: Artist diagram displaying a general algorithm for treatment of patients with scoliosis, coronal malalignment, and pelvic obliquity. In patients with pelvic obliquity in which the spine is flexible and aligned, full correction of the curve may lead to significant coronal decompensation as the scoliotic curve may be compensatory. In some of these patients, the addition of a shoe lift will allow the flexible spine to relax and may improve alignment and deformity-related symptoms. If the spine is rigid as is more common in adults, a shoe lift may be poorly tolerated and may not be effective in rebalancing the spine. These patients may require incomplete curve corrections and, sometimes, a shoe lift as well depending upon the final standing alignment. (PO: Pelvic obliquity).

postoperative standing films are further recommended to allow further coronal adjustments if needed. The patient's ability to compensate for rigid coronal malalignment is even less than for sagittal malalignment as no direct correlate exists for pelvic retroversion in the coronal plane.

SUMMARY

The pelvis plays a critical role in upright balanced sitting and standing postures, and recent data demonstrate that failure to account for pelvic alignment when treating spinal deformity increases the risk of residual spinal deformity and long-term treatment failure. Pelvic alignment including PI, PT, SS, and pelvic obliquity must be evaluated by treating physicians in addition to more traditional measures such as SVA, LL, TK, and regional scoliotic curves. Particular attention must be paid to PT, which is a dynamic pelvic parameter reflective of pelvic retroversion, as increased PT implies residual postoperative spinal

deformity and will negatively affect function and, thus, postoperative outcomes.

When planning for spinal reconstructive procedures, it is important to consider that preoperative planning formulas that do not evaluate pelvic parameters, especially PI and PT, may be inaccurate and increase the risk of postoperative malalignment. Normalization of the PT requires more angular correction than predicted by the Ondra formula. Preoperative planning formulas such as the one developed by Lafage et al. that include PI, PT, LL, TK, and patient age are the most accurate.⁴⁷ The location of the osteotomy along the spine is also an important consideration when attempting to normalize the PT, as a more caudal osteotomy is associated with greater PT reduction. It is also important to consider that spinal segments not incorporated within the fusion may increase kyphosis after lumbar PSO. These unfavorable changes are more common in patients with higher PI, greater preoperative SSM, and older age.

Pelvic obliquity and the associated etiology must be accounted for in strategies for coronal plane correction. Correction of lumbar curve in the setting of pelvic obliquity may generate postoperative coronal decompensation. If the pelvic obliquity is due to a compensatory mechanism for the spinal coronal malalignment, correction of the spine may restore the pelvic coronal malalignment. If the spine is flexible, the shoe lift may yield a considerable amount of spinal coronal correction. However, if the spine is rigid, surgery is likely necessary, in conjunction with a shoe insert. Intraoperative full-cassette radiographs should be used to evaluate the coronal alignment and account for the patient's pelvic obliquity.

Global spinopelvic alignment relationships are becoming more important and are needed for a complete assessment of the patient's spinal deformity. It has been shown, as mentioned earlier, that the spinal regions are interrelated.^{3,5,11,16,48} A global approach is needed to correctly treat spinal deformity, despite where the actual pathology may be located within the spinal column. Lumbar spinal deformity may affect cervical alignment and vice versa. A marked LL (determined by PI) and TK will lead to a pronounced CL in order to maintain horizontal gaze. This has significant implications for patients with fixed alignment of the cervical spine (e.g. post-fusion) where modifications and compensation for malalignment in other regions of the spine cannot be taken on by the cervical region. Such considerations should also be taken into account in the setting of cervical disc arthroplasty, where the amount of cervical lordosis should be patient specific. Furthermore, cervical lordosis can be considered, similar to TK and LL, as an adaptive spinal segment to global alignment. When LL and TK are adapted to the patient's PI, cervical lordosis will be proportional to the other curves. In the setting of anterior malalignment (driven by a loss of LL and/or an increase in TK), cervical lordosis can be seen as a compensatory mechanism. This reciprocal change of cervical lordosis has been reported after realignment procedure for patients with significant anterior malalignment.^{50,51}

The SA of the cervical spine is becoming a very important parameter as the same concepts used to so successfully characterize the effect of thoracolumbar alignment on outcomes are applied to the cervical spine. Currently, there is only one study to date correlating cervical regional SA to HRQOL outcome scores.⁵² Tang et al.⁵² found that patients with increasing cervical SVA had poorer HRQOL scores and a cervical SVA > 4 cm is correlated to worse

health-related outcomes. These findings are the first step toward a comprehensive assessment of spinal malalignment and its effect on HRQOL. Furthermore, there is not a single agreed upon standard to measure cervical sagittal alignment.⁵³ Hardacker has suggested that the C2 plumb line could be used as a standard measure.⁵³ Future work will allow exploration and clarification into the exact relationship between the cervical spine and global sagittal alignment as well as their impact on HRQOL.

KEY POINTS

- Pelvic alignment including PI, PT, SS, and pelvic obliquity must be evaluated by the treating physicians in addition to more traditional measures such as SVA, LL, TK, and regional scoliotic curves. Failure to account for pelvic alignment when treating spinal deformity increases the risk of residual spinal deformity and treatment failure.
- Preoperative planning formulas that do not evaluate pelvic parameters, especially PI and PT, may be inaccurate, and increase the risk of postoperative malalignment; formulas that include PI, PT, LL, TK, and patient age are the most accurate.
- Pelvic obliquity and the associated etiology must be accounted for in strategies for coronal plane correction, as correction of lumbar curves in the setting of pelvic obliquity may generate postoperative coronal decompensation.
- The regional spinal segments are not independent of one another, and significant correlation of alignment exists from the pelvis to the cervical spine.
- When LL and TK are adapted to the patient's PI, cervical lordosis will be proportional to the other curves; however, in the case of anterior malalignment, cervical lordosis can be seen as a compensatory mechanism.

INTRODUCTION

Adult spinal deformity encompasses a broad spectrum of pathology, including adult sequelae of persistent idiopathic scoliosis, “de novo” scoliosis secondary to age-related degenerative changes, sagittal plane deformity, post-traumatic or iatrogenic postsurgical deformity, and scoliosis secondary to metabolic bone disease (mostly osteoporosis). Adult degenerative scoliosis (ADS) or “de novo” scoliosis develops after skeletal maturity, with a coronal Cobb angle $>10^\circ$. It is secondary to asymmetric degenerative changes, without history of scoliosis in childhood or adolescence, and it typically presents in the sixth or seventh decade of life.^{1,2} Osteoporosis and micro/macro-vertebral compression fracture may contribute to overall degenerative process and development of ADS.² Adult degenerative scoliosis is rarely seen before the age of 40, in which case it likely represents progression of undiagnosed adolescent idiopathic scoliosis (AIS) that developed before skeletal maturity but became symptomatic later in adult life.^{1,2} Curves in ADS tend to be more rigid than in AIS and typically progress by 1–6° per year (average 3°).^{1,3} The prevalence of adult scoliosis among the elderly in a report from 2005 was 68%, which was higher than the previously reported prevalence of 32%.^{4,5} The report

from 2005 noted that, although many of the patients with adult scoliosis had pain and dysfunction, there was a large group that had no symptoms.⁴

Adults with scoliosis who are symptomatic characteristically present with pain and disability.^{2,6–8} This is often secondary to associated degenerative changes including degenerative disc disease, spinal and foraminal stenosis, facet arthropathy, spondylolisthesis, rotational subluxation, and rigidity within deformity.⁹ Therefore, clinical presentation is also variable and includes axial back pain, radiculopathy, neurogenic claudication, neurologic deficit, and progressive cosmetic deformity.^{8,10} Although radiographic features and cosmesis generally guide the treatment of AIS, the most important guiding principles for adult spinal deformity treatment are pain and disability.¹¹ Positive sagittal malalignment has the strongest correlation with pain and disability in ADS.^{12,13} Treatment of adult deformity is becoming an increasingly important part of spine practice due to the aging population and rising expectations for quality of life. Asymptomatic patients usually need no treatment, although periodic follow-up may be useful to assess for curve progression. In symptomatic adult scoliosis patients, although current literature suggests that surgery has the potential to offer significant improvement

in pain and disability compared to nonoperative treatment, nonoperative treatment should typically be the first-line treatment in the absence of significant and/or progressive neurologic deficit or rapidly progressive deformity.^{5,14,15}

Nonoperative treatments for adult deformity include physical therapy, chiropractic manipulation, pain management, injections, yoga, acupuncture, and medications. However, there are few reports in the literature focused on nonoperative treatment, and there is no consensus on nonsurgical treatment paradigms.^{6,16-18} In contrast, for lumbar degenerative disease without deformity, although there is lack of consensus on treatment paradigm, there is at least extensive literature addressing nonoperative treatment options.^{17,19-21} There are also several reports focused on nonsurgical treatment for adolescent spinal deformity, including bracing and exercise.^{17,22,23} However, there is a paucity of information on the nonoperative management of adult deformity.

Everett et al. in their systemic literature review of non-surgical treatment in adult scoliosis in 2007 found that evidence for nonoperative treatment of adult scoliosis was lacking based on a review of articles published from 1996 to 2007.¹⁶ There were only two articles on bracing that met the criteria of inclusion and only three articles were reviewed for physical therapy, of which one was a case series. There were two case series for chiropractic manipulation, and only one article focused on injections. These articles provided only weak Level IV evidence, except for the article on injections, which provided Level III evidence. The review of Everett et al. concluded that, although nonoperative treatment may appear to be a helpful option, there was significant lack of evidence in the literature to support it.¹⁶ Since this review, there have been a few notable additions to the literature regarding nonoperative treatment. Glassman et al. evaluated nonoperative treatment of adult spinal deformity in a series of articles addressing nonsurgical resource utilization, cost-benefit, and patient-based health outcome measures.^{6,17,18} There have also been efforts to develop predictive models based on clinical symptoms and radiographic parameters to determine which patients may be more likely to benefit from operative versus nonoperative treatment for the management of symptomatic adult spine deformity.^{5,6,8,14,15,24,25}

In an effort to study nonsurgical resource utilization in adult deformity, Glassman et al.¹⁷ in 2006 reviewed the enrollment data for 1,061 patients who entered into a prospective multicenter study for adult spinal deformity between January 2002 and June 2004. The mean age

was 48.2 years and enrollment criteria included: scoliosis $>30^\circ$, sagittal plane deformity with kyphosis $>60^\circ$, sagittal imbalance >6 cm, or history of scoliosis surgery >18 months before enrollment. Patients were enrolled in either a surgical arm ($n = 476$) or a nonsurgical arm ($n = 585$). Patients in the surgical arm were scheduled for surgery. Patients in the nonsurgical arm were divided into low-symptom and high-symptom subgroups based on an age-adjusted Oswestry Disability Index (ODI) score of less than or >20 . Patient-based health status measures, including Short Form-12 (SF-12), Scoliosis Research Society questionnaire-29 (SRS-29), and ODI were used for assessment. The operative and nonoperative groups were similar in terms of gender, curve type, and history of previous surgery. The high-symptom nonsurgical group was similar to the surgical group in terms of patient-related health outcome measures. One of the concerns regarding the study design was that adult deformity patients referred to a spine surgeon might be more symptomatic and may not represent the general adult deformity population, with the possibility of the majority of adult deformity patients being treated expectantly by primary care physicians and, therefore, leading to bias toward greater utilization of resources. This concern was offset to some extent by stratifying the nonsurgical patients into high- and low-symptom groups based on standardized health status measures and the finding that the low-symptom group was similar to the general population based on normalized SF-12 values. Resource utilization was assessed by recording the use of aerobic exercises, aquatic therapy, strength training, postural training, body mechanics physical training, analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), narcotics, pain management, epidural injections, facet or nerve blocks, bracing, and bed rest. The high-symptom group, which was more similar to the surgical group, was found to utilize significantly greater resources in general. The high-symptom group utilized pain management most (55%), followed by exercise and analgesics or NSAIDs (38% each). Notably, although the low-symptom nonsurgical group, which had similar standardized health measures as the general population, also had substantial resource utilization, with approximately 70% of these patients receiving nonoperative treatment related to their spinal deformity. The most frequently used treatments in the low-symptom group were exercise (33%), analgesics or NSAIDs (24%), and pain management (22%). Furthermore, of note was that, whereas the low-symptom group had more commonly not received any treatment prior

to enrollment, the high-symptom group had a significant history of previous resource utilization, including narcotics, epidural injections, exercise, and pain management referral, prior to enrollment in the study. Another finding was that the low-symptom group had a high percentage of adult patients with idiopathic scoliosis and the high-symptom group had a higher percentage of patients with sagittal plane deformity, which is consistent with the literature that sagittal plane deformity can have a particularly high impact on health-related quality of life (HRQOL). Patients in the low-symptoms group, once they enrolled in the study, were encouraged to increase use of the exercise method and decrease use of narcotics and pain management. In the high-symptoms group, there was an increase use of analgesics, pain management, and bed rest.

In a retrospective review of prospectively, consecutively enrolled patients ($n = 1,568$; 640 surgical and 940 nonsurgical), Glassman et al. in 2007 assessed selection criteria for operative versus nonoperative treatment of adult deformity patients.⁶ Case-control matching, which was one of the two analytical methods used, led to 161 surgical-nonsurgical pairs (322 patients) matched for further analysis. There were 247 patients for the logistic regression analysis, which was the second method of analysis. They stratified the parameters that influenced surgical decision for the surgeons and patients into groups, including preoperative factors, radiographic measures, clinical symptoms, functional limitations, and appearance, or social issues. They found that preoperative risk factors, including higher body mass index (BMI), history of cardiac disease, and a poor General Health SF-12 subscale score differed significantly between the surgical and nonsurgical groups. Nonsurgical patients had greater preoperative risk factors. Based on logistic regression analysis, younger patients were more likely to be treated surgically. The only radiographic parameters associated with increased likelihood of surgical treatment were greater thoracic and thoracolumbar/lumbar Cobb angles and great thoracolumbar/lumbar apical vertebral translation. Multiple studies have shown that thoracolumbar curves are associated with greater severity of symptoms compared with thoracic curves, but there was no correlation between curve magnitude and degree of pain.^{12,26} An interesting finding was the lack of strong correlation between positive sagittal balance and surgical treatment, although sagittal imbalance has been shown to have a particularly strong correlation with pain and disability in ADS and restoration

of sagittal alignment remains a high priority in spinal deformity surgery.^{12,13,26,27} This may be because patients with sagittal imbalance may have been excluded because their primary diagnosis was not adult idiopathic scoliosis (one of the inclusion criteria of the study). It is also possible that the propensity score may have inadvertently matched the surgical and nonsurgical groups for sagittal balance. The surgical patients had more frequent leg pain (47% vs. 35%), greater mean level of daily back pain, and more frequent moderate-to-severe back pain in the last 6 months. One of the interesting findings of the study was that the patient's perception of appearance and social function influenced their decision to pursue surgical treatment.

In another study in 2010, Glassman et al. studied the costs and benefits of nonoperative management for adult scoliosis.¹⁸ A total of 123 patients with a mean age of 53.3 years (range: (18–79 years) was evaluated. Patients were segregated based on their pretreatment ODI into a low-symptom group ($ODI \leq 20$), mid-symptom group ($ODI = 21-40$) or high-symptom group ($ODI \geq 40$). Nonoperative treatment included medication, exercise therapy, modality physical therapy, chiropractic treatment, pain management referrals, and injections. Among the 68 adult scoliosis patients who received nonoperative treatment, there was no significant change in any of the HRQOL outcome parameters over 2 years. This trend was also observed in the stratified groups based on pretreatment severity. The mean nonoperative treatment cost over the 2-year period was \$10,815, with an average cost of \$9,704 for patients in the low-symptom group, \$11,116 for patients in the mid-symptom group, and \$14,022 for patients in the high-symptom group. This study had limitations, including that the study population consisted of patients referred to a tertiary spine center for the evaluation of their scoliosis and, therefore, may not represent the general population of adult scoliosis patients. Another issue was that the study was not well delineated in terms of indication or specific technique, which raised the possibility that a subgroup of patients may benefit from a clearly defined nonoperative regimen and a possibility that some of the patients may have deteriorated if they did not have the benefit of nonoperative treatments.

PATIENT EDUCATION

Including the patient in discussing the potential causes of pain and the disease process is important in the management of adult deformity. This gives the physician an

opportunity to understand the symptoms better and, at the same time, helps patients better understand the potential reasons for their pain, in turn making them more active participants in their treatment plan. This also provides the opportunity to discuss risk factors and life style modifications, such as smoking cessation, weight loss in obese patients, and treatment of osteoporosis. It is also important to address these factors while the patient is undergoing nonoperative treatment, because they may complicate surgical intervention, if needed, in the future. This discussion also provides the opportunity to assess patient motivation and commitment to work toward the goals of eliminating or reducing the risk factors and achieving better functional lifestyle, which may be important guiding factors for any future surgical intervention. Possible therapies should be recommended after considering and discussing the natural history of adult spine deformity, history of previously received therapy, and risk and benefits of operative and nonoperative treatment. Although current literature suggests that surgical intervention may offer better outcomes with regard to pain and disability in adult deformity patients, nonoperative treatment should typically be the first line of therapy for most adult deformity patients.^{5,6,15}

Factors that may lead to transition from nonoperative treatment to operative treatment are not fully understood. Failure of conservative treatment, severe radiculopathy, neurologic deficit, and positive sagittal malalignment have been associated with this transition.^{6,8,24} Several factors should be considered before making the transition toward surgical intervention, including severity of symptoms, functionality and quality of life, health of the patient, and the patient's understanding of and willingness to accept the risks of surgery.⁵ There should be a clear discussion with patients regarding potential risks and benefits associated with different treatment options, especially for surgical interventions, such that both the patient and surgeon have similar expectations.²⁴ It is also important to recognize that although operative treatment of symptomatic adult deformity may offer the potential for better outcomes, these assessment are based on averages across large groups of patients and not all patients will have similar outcomes. The outcomes vary from significant improvement to unchanged or worsening of symptoms in some cases.²⁵

SMOKING

Cigarette smoking has a known association with increased risk of back pain and degenerative disc disease.^{28,29} Moreover, the adverse impact of cigarette smoking on spinal

fusion is well known.^{30,31} Nearly 19% of Americans continue to smoke, despite smoking rates declining.³² Nicotine is an established cause for the addictive component and adverse effects of smoking.³³ It causes reduced blood supply, tissue hypoxia, and affects arteriole endothelial receptors leading to reduced bone metabolic activity.^{34,35} It also causes selective depletion of bone marrow β -lymphocytes and decreased calcium absorption, and interferes with osteoblastic function, all of which may be contributing factor for decreased bone formation.^{36,37} Elevated levels of proinflammatory mediators in smokers may amplify pain.³⁸ A recent meta-analysis of 40 studies showed that smoking was associated with increased prevalence of low back pain and increased risk of having chronic back pain or disabling back pain.²⁸ Smoking may also exacerbate postmenopausal and aging-related bone loss. Postmenopausal women who smoke are more prone to vertebral fractures and low vertebral bone mineral density.³³

Glassman et al. retrospectively studied the effects of cigarette smoking and smoking cessation on spinal fusion.³⁰ The nonunion rate was 14.2% for nonsmokers versus 26.5% in patients who continued to smoke after surgery. For patients who quit smoking <6 months, the nonunion rate was 17.1%, which was slightly better than the 18.2% in patients who quit for 1–6 months after surgery. Both rates were better than in smokers (26.5%) but higher in comparison to nonsmokers (14.2%). Successful postoperative smoking cessation was related to the amount of smoking before surgery and ability to quit smoking preoperatively, but improved outcomes were related to postoperative rather than preoperative smoking cessation. Analysis of return-to-work data showed that patients who quit smoking for > 6 months postoperatively were more likely to go back to full or light duty work (74.6%) than nonquitters (53.6%).³⁰

The most common perioperative complications attributed to smoking are wound-healing, infection, and cardiopulmonary complications.^{33,39,40} Although there are no definite guidelines for smoking cessation, it has been shown that longer periods of smoking cessation decrease the incidence of postoperative complication.^{33,39–41} Smokers should be encouraged and counseled to quit smoking as it has been shown to have an association with degenerative disc disease and back pain. Patients should be informed that smoking also has adverse effects on spine fusion, in the event that their deformity warrants it and they wish to pursue surgery in the future. Patients should be encour-

aged to discuss smoking cessation with their primary care physician, as smoking interventions such as counseling and pharmacotherapy have shown to increase the chances of abstinence.⁴² Nicotine is primarily metabolized in liver, and its metabolite cotinine is used to screen recent smoking. It has a half-life of 14–20 hours and can be detected in urine for approximately 10 days after cessation.³³

MORBID OBESITY

Obesity is a major health problem in the United States and has reached epidemic proportion. Overweight is defined as a BMI of 25.0–29.9, and a BMI of >30.0 is considered to be obesity.⁴³ The World Health Organization grades obesity as grade 1 (BMI 30–34.9), grade 2 (BMI 35–39.9), and grade 3 or morbid obesity (BMI ≥ 40).⁴⁴ The prevalence of obesity in the United States is high and, except for men aged 20–29 years, it is over 30%. Flegal et al. reported the prevalence of obesity to be 32.2% in adult men and 35.5% in adult women.⁴⁵ These proportions continue to rise although, in the last decade, the rate has slowed down especially for women and possibly for men in comparison to the previous decade.⁴⁵ Obesity has been shown to be associated with multiple health problems including diabetes, hypertension, high cholesterol, stroke, heart disease, certain cancers, and arthritis. Higher grades of obesity have been associated with excess mortality, particularly from cardiovascular disease, diabetes, and obesity-related cancers.^{46,47} Obesity has also been shown to be an independent risk factor for low back pain and degenerative spine disease, especially of the lumbar spine.^{48,49}

With regard to spine surgery, there are only limited studies investigating the effect of obesity on spine surgery outcomes. Many studies have found that there is no difference between the clinical outcomes for back surgery for proper indications.^{50–52} Initial studies did not include patient-directed quality of life measures, but Djurasovic et al. in their study included the Short Form-36 (SF-36), General Health Instrument, and ODI in assessing patient outcomes.⁵¹ They concluded that obese patients with proper indications for surgery achieve similar benefits and improvement with lumbar fusion as nonobese patients. Morbid obesity has also been associated with higher hospital costs and higher complication rates, with wound infection being the most common complication followed by pulmonary complications.^{51,53,54} Djurasovic et al., in their study, found a statistically significant increase in wound-related complications in obese patients (5.5%).⁵¹

There have been few studies evaluating the effect of obesity on scoliosis surgery and most of them are for

idiopathic scoliosis surgery. Upasani et al. in 2008 in a multicenter retrospective review of 241 patients examined the effect of BMI on surgical outcomes.⁵² Although obese patients (BMI ≥ 35) had increased preoperative kyphosis, it did not affect the surgical goal of achieving similar correction of the deformity. Another study analyzing proximal junctional kyphosis (PJK) in primary adult deformity surgery found that a PJK $\geq 20^\circ$ in primary adult idiopathic/degenerative scoliosis was associated with older age, shorter constructs starting in the lower thoracic spine, obesity, and fusion to the sacrum.⁵⁵ Although a recent report suggests that obesity is not related to increased risk of morbidity in anterior lumbar surgery, obese patients have significantly longer duration of anterior exposure, longer duration of the anterior surgery, longer length of anterior incision, and more depth from skin to fascia and from fascia to spine compared with nonobese patients.⁵⁶

Although obesity itself is not necessarily a contradiction for surgical intervention, if indicated in the obese patient, the importance of weight loss should be discussed with patients in the context of overall health and beneficial effects for the spine and postoperative rehabilitation. In morbidly obese patients with significant comorbidities, consultation with bariatric surgery can be an option to consider. Addressing obesity as part of a nonoperative treatment approach may reduce load on the spine and improve symptoms in addition to helping improve the ability of the patient to tolerate surgical treatment should this be warranted and pursued in the future.

OSTEOPOROSIS

Osteoporosis/osteopenia may play a role in adult spine deformity and its progression, but it has been suggested that there is not a significant role for osteoporosis/osteopenia in the progression of ADS curve.^{57,58} It has been shown that postmenopausal bone loss is similar in both adult scoliosis patients and the general population.⁵⁸ However, fractures secondary to osteoporosis may cause an asymmetric configuration, which may lead to kyphosis or scoliosis or both and may occur in preexisting scoliosis.²

Elderly patients should get work up for osteoporosis including dual-energy X-ray absorptiometry and be treated accordingly. Notably, it has been suggested that degenerative scoliosis may cause false elevation of spinal bone mineral density.⁵⁹

PHYSICAL THERAPY

There is Level IV, weak evidence for the use of physical therapy as a part of nonoperative treatment of adult

deformity.¹⁶ In a clinical study of approximately 30 patients with degenerative scoliosis, patients underwent an FED (fixation, elongation, and de-rotation) type of physical therapy. The patients were initially treated with heat, followed by three-dimensional fixation in an FED unit, with elongation and de-rotation through traction and corrective pressures.⁶⁰ It was performed intermittently or continuously with periods of relaxation. Patients received 60 cycles of therapy. Patients were treated with NSAIDs as needed for pain. The authors found a statistically significant improvement of pain and curve improvement.⁶⁰ However, the study had significant limitations, since the traction protocol, number of patients by degree of curve magnitude, and the independence of radiograph reviewers were not described in the study, making the study conclusions difficult to corroborate.¹⁶

In another study of 69 skeletally mature patients, specific side-shift exercises did not show any significant improvement of symptoms.^{16,61} In another study, 8 weeks of aquatic therapy decreased levels of back pain and disability, increased quality of life, and improved health-related fitness in adults with chronic low back pain. A dose-dependent response effect was observed in some parameters, with greater benefits with 3 days of exercise per week compared with 2 days of exercise per week.⁶²

BRACING

Thoracolumbosacral orthotics and lumbosacral orthotics have no significant role in the nonoperative management of adult spinal deformity.^{16,63} Although these braces may provide short-term pain control, long-term use may lead to muscle deconditioning. In addition, bracing does not have a significant effect on curve progression, as it is not secondary to spinal growth in this population.^{1,16,63,64}

CHIROPRACTIC AND PILATES THERAPY

The best evidence for chiropractic manipulation is very weak and Level IV case studies.¹⁶ In those studies, it was found to be helpful for temporary pain relief and possible to slow curve progression.^{65,66} In one of the case studies, it was found that the addition of Pilates to chiropractic care improved pain relief, and the authors reported that the sacro-occipital technique is an effective chiropractic maneuver in scoliosis.⁶⁵

PHARMACOLOGIC THERAPY

Pharmacologic agents such as NSAIDs, narcotic analgesics, muscle relaxers, and anticonvulsants have been used

to treat spinal pain. There is no specific literature for adult spinal deformity patients, but there are data regarding their use in spinal pain.

There is good evidence for the efficacy of NSAIDs for acute back pain, but the evidence is less convincing for chronic back pain.⁶⁷⁻⁷⁰ There is no clear evidence that opioid analgesics are more effective than NSAIDs.^{67,69} No single type of NSAID appears to be more effective than the others.^{67,69} Patients and physicians should be aware of the common gastrointestinal and renal toxicity associated with NSAIDs. Nonsteroidal anti-inflammatory drug-induced acute renal failure is second only to aminoglycoside-induced renal failure and accounts for 15% of all drug-induced renal failure.^{68,71} It occurs usually secondary to prostaglandin inhibition and is often, but not always, reversible. Gastrointestinal toxicity occurs in approximately 1-2% of NSAID users.^{68,72} There is also concern of cardiovascular complications.^{68,73} Often, NSAIDs are first-line treatments of spinal pain. Although there is only limited evidence regarding acetaminophen use in comparison to NSAIDs, it may also be used for mild back pain, especially among patients who cannot tolerate NSAIDs.⁶⁷

Tramadol exhibits weak opioid effects and inhibits serotonin and norepinephrine reuptake. It has been shown to be effective for short-term improvement of pain and function in the treatment of low back pain, but there are no good data regarding long-term use.^{69,74} Major side effects include dizziness, nausea, sedation, constipation, and headache. In addition, its use above the recommended dose is associated with seizures.⁶⁸

Opioids can be used in the treatment of chronic spine pain, but should be avoided if possible. There is no good evidence that opioids are more effective than NSAIDs.⁷⁰ There is only one trial that compared opioids with other analgesics, which was naproxen.^{69,74} Although it had greater pain relief, it did not lead to greater improvement of patient activity. Opioids have a potentially greater risk of side effects, decreasing effectiveness related to habituation when used long term, and have a high potential for addiction.⁶⁸⁻⁷⁰ A comparison of patients treated with narcotic versus non-narcotic medication over 2 years showed no significant difference in HRQOL.¹⁸

Muscle relaxers have been reported to be moderately superior to placebo for short-term pain relief, but are less effective than NSAIDs and were associated with more side effects.⁷⁵ The side effects are often central nervous system related, and mainly include sedation and dizziness. Anticonvulsant medications including gabapentin

and carbamazepine have been shown to have some effect on radiculopathy. There are limited studies showing modest improvements in pain scores when compared with placebo.⁶⁹ Side effects for gabapentin include drowsiness, loss of energy, and dizziness.⁶⁹ Pregabalin works in a similar way and has been reported to have some benefit, but the data are limited.⁶⁸ Antidepressants have also been used for chronic back pain and there is some evidence that these are more effective than placebo for pain relief, but there is no evidence of clear benefit of functional outcomes.^{68,69}

INJECTIONS

Interventional pain management is an emerging subspecialty in the management of spine pain. There is limited literature regarding the role of injections for adult spine deformity-related pain as shown in the systemic review by Everett et al. in which they could only find one article for epidural injections that met the criteria for the study.¹⁶ This was a retrospective study of 61 patients with degenerative scoliosis (coronal Cobb angle $> 10^\circ$) and radicular complaints by Cooper et al. that explored the role of fluoroscopic transforaminal epidural steroid injection (ESI) for the radicular pain. They found these injections to be effective treatment options for patients with degenerative lumbar scoliotic stenosis and radiculopathy.⁷⁶ In their study, successful outcomes were reported in approximately 60% of patients at 1 week following injection, 56% at 1 month following injection, 37% at 1 year following injection, and 27% at 2 years following injection. Although there are very limited data for the role of ESI for adult spine deformity-related pain, it is the strongest (Level III) among the different nonoperative treatment modalities, as there is only Level IV evidence for other nonoperative treatment modalities for adult spine deformity.¹⁶

There is growing evidence for the role of interventional pain management for pain from degenerative spine disease, but more so for short-term relief than long-term relief. Pain in adult spine deformity is multifactorial and may be secondary to muscle fatigue and spasm, spinal imbalance, facet arthropathy, degenerative disc disease, foraminal and central canal stenosis, and spondylolisthesis.^{2,10,77} Therefore, interventional pain management procedures, including facet joint injections, epidural injections, selective transforaminal nerve block, trigger point injections, and sacroiliac joint injections, may be helpful for pain management in some adults with spinal deformity. Many of the causes of the spinal pain in adult deformity

patients are acute recurrent problems that are characterized by periods of quiescence with episodic flare-ups, and injections could be particularly helpful in these patients in temporarily easing symptoms during the episodes of flare-up.

Epidural injections, selective nerve root blocks, and facet injections may be effective for both therapeutic and diagnostic purposes.^{78,79} These can be diagnostic by helping to localize the cause of pain, if there is question regarding its source. There is better evidence for the role of ESI in disc herniation/lumbar radiculitis than spinal stenosis, and no clear evidence for axial or discogenic back pain, and the therapeutic benefit is better in short-term than the long-term.^{78,79} Most studies show no difference in surgical rates between patients treated with ESI and control patients; however, some randomized studies conducted by spine surgeons showed, in some patients, that the strategic use of ESI may help to prevent or delay the need for surgery.^{80,81}

The American Society of Intervention Pain Physicians in 2013 published the revised guidelines for interventional pain management.⁷⁸ For epidural injections (caudal, interlaminar, and transforaminal) in the diagnostic phase, a patient may receive two procedures at intervals of no sooner than 2 weeks or, preferably, 4 weeks. In the therapeutic phase, the recommended frequency of interventional techniques should be ≥ 2 months between each injection, provided that $> 50\%$ relief is obtained for 2 months. If neural blockade is applied to different regions, the guidelines recommend performing these at intervals of no sooner than 1 week and preferably 2 weeks for most types of procedures, and the therapeutic frequency may remain at intervals of at least 2 months for each region. However, the guidelines suggest that all regions can be treated at the same time, if all procedures can be performed safely. Cervical and thoracic regions are considered as one region; lumbar and sacral are considered as one region. Epidural injections should be repeated only as medically necessary, and are recommended to be limited to a maximum of 4 times per year.⁷⁸ For facet blocks, the recommendation is similar for both diagnostic and therapeutic purposes, with suggested frequency of 2- to 3-month intervals between injections, provided that $> 50\%$ relief is obtained for 2 months, with a maximum of 4 times for local anesthetic and steroid blocks over a period of 1 year per region. Under unusual circumstances, with a recurrent injury or cervicogenic headache, procedures may be repeated 6 times in a year after stabilization in the treatment phase.⁷⁸ The recommendations for

sacroiliac joint injections are similar, provided that there is > 50% relief in symptoms for at least 6 weeks.⁷⁸

OTHERS

Other nontraditional treatment modalities like *Yoga*, massage therapy, acupuncture,⁸² transcutaneous electrical nerve stimulation, and percutaneous electrical nerve stimulation may be tried and pursued if the patient perceives benefit, but presently, there is no clear evidence to support these approaches.

OPERATIVE VERSUS NONOPERATIVE TREATMENT

Multiple studies have shown long-term benefit with surgical treatment of adult deformity.^{5,8,14,15,24,25} This contrasts with the lack of good-quality data to support nonoperative treatment.^{6,16,18} Smith et al., in their recent studies, evaluated the role of surgical treatment in adult spinal deformity with regard to leg pain and back pain in two separate studies.^{14,15} In the first study analyzing improvement of back pain with operative and nonoperative treatment in adults with scoliosis, Smith et al. found that, despite starting with significantly greater back pain and disability and worse health status, surgically treated patients had significantly better outcome at the 2-year follow-up compared with patients treated nonoperatively.¹⁵ Of 317 patients with back pain, 147 (46%) were managed surgically and 170 (54%) were managed nonsurgically. Compared with nonsurgical patients, surgical patients had higher base line mean numeric rating score (NRS) for back pain (6.3 vs. 4.8; $P < 0.001$), higher mean ODI score (35 vs. 24; $P < 0.001$), and lower mean SRS-22 scores (3.1 vs. 3.4; $P < 0.001$). At the 2 years follow-up nonsurgical patients did not have significant change in NRS score for back pain ($P = 0.9$), ODI ($P = 0.7$), or SRS-22 ($P = 0.9$), whereas surgically treated patients had significant improvement in all three parameters, with NRS score of 6.3–2.6 ($P < 0.001$), ODI of 35–20 ($P < 0.001$), and SRS-22 of 3.1–3.8 ($P < 0.001$). Furthermore, compared to nonsurgical patients, at the time of the 2-year follow-up, surgically treated patients had better NRS, ODI, and SRS-22 scores.¹⁵

Similarly, in the second study that analyzed leg pain in adult deformity patients based on a retrospective review of prospectively collected data with 2-year follow-up, Smith et al. concluded that there was significant improvement in mean NRS score for leg pain and ODI in

surgically treated patients. Nonsurgically treated patients showed no significant improvement at the 2-year follow-up.¹⁴

In deciding between an operative and nonoperative treatment approach, it should be recognized that surgery has significant associated risks with reported complication rates ranging from 10% to 96%.²⁴ In assessing the risks versus benefits of surgery for adult scoliosis, Smith et al. reported a strong association between complication rates and patient age.⁵ The total complication rates for the age groups of 25–44, 45–64, and 65–85 years were 17%, 42%, and 71% respectively, including major complication rates of 6%, 15%, and 29%, respectively.⁵ The older patients had a significantly greater degree of pain, disability, and worse health status at baseline. Patients in all age groups showed significant improvement in disability at 2-year follow-up, with ODI showing significantly greater improvement in older patients. Despite high complication rates in the older age group, at the 2-year follow-up, the health outcome measures were indistinguishable from other groups, suggesting that, despite having greater risk of complications from adult deformity surgery, the elderly group also had a better chance of greater improvement in disability and pain compared to younger patients.⁵

CONCLUSION

There are high- and low-symptom groups among adult deformity patients, and both groups appear to utilize nonsurgical resources. Although evidence is still lacking, conservative treatment is a valuable option in the treatment of adult deformity. The objective of nonoperative treatment is relief from pain and improvement in the functional capacity of the patient, and a trial of conservative treatment should be done before considering surgical treatment in most adult deformity patients. Some patients with severe disabling pain, who may have already exhausted all conservative modalities before seeing a spine surgeon or patients with severe radiculopathy symptoms, neurogenic claudication, or neurologic deficit, may be candidates for operative treatment without trying further conservative treatment. When deciding between operative versus nonoperative treatment approaches, several factors should be considered, including severity of symptoms, quality of life, overall health of the patient, and understanding and willingness of the patient to accept the risks associated with surgery. The current literature has several reasonable quality studies that provide risk and benefit

assessment of operative treatment of adult spine deformity, but there is still a paucity of literature regarding nonoperative treatments. More clinical research is needed to clarify the optimal nonoperative treatment paradigm.

KEY POINTS

- There is a lack of high-quality data for nonoperative treatment options for adult spinal deformity.
- There is significant utilization of nonoperative treatment resources by adult deformity patients.
- No lasting improvement in HRQOL has been reported in adult spinal deformity patients undergoing nonoperative treatment when compared to untreated patients.
- Prospective studies designed to specify indications and guidelines for nonoperative treatment are needed.

INTRODUCTION

Spine surgery for the management of adult deformity has increased significantly over the past two decades. It is well recognized that adult spinal deformity has a higher rate of complications than other types of spine surgery. Surgical procedures for adult deformity often include long segment fusions, anterior/posterior combined procedures, and surgery that is being revised from earlier procedures—all of this increases the physiologic toll that accompanies the surgery. The purpose of this chapter is to review the process of preoperative preparation of adults for spinal deformity surgery.

Spinal deformity surgery in the adult presents challenges to the spine surgeon in many different fashions. These surgeries are often larger in scope than most adult spinal surgeries and present a set of complications that is somewhat expanded compared to spinal surgery done on a smaller scale. Awareness of the potential complications allows the spinal surgeon to lessen the chance that they will occur. This requires a focus not just on the technical aspects of the surgical procedure, but on the overall medical condition of the patient. Often, complications are seen in other organ systems after adult spinal deformity surgery—this necessitates a multidisciplinary approach to these patients often starting prior to the surgical

procedure. The consultants from various fields can play a role preoperatively in identification of potential problems and maximization of the patient's health status prior to surgery. Much of the information in this chapter is drawn from the literature of respective fields of medicine. Older adults in the United States are increasing physically active into their older years and wish to remain so. The aging population also, however, accumulates comorbidities. These comorbidities play an important role in the stratification of risk perioperatively. Up to 68% of the population older than 60 has some form of spinal deformity, which can result in the limitation of activity.¹ The goals of deformity surgery in broad terms are to restore sagittal alignment and to decompress stenosis. The goal of this chapter is to draw attention to conditions that potentially can affect perioperative complications and patient outcomes. These conditions may be modifiable in some cases. In the event that they are, they generally should be optimized prior to surgery. Attention to and optimization of medical conditions allow complex surgery to be performed on this elderly population, who have been found to benefit substantially from deformity correction.² The cardiac, pulmonary, psychiatric, and nutritional systems can all potentially be optimized prior to surgery. In addition, this is often an aging population and the evaluation of bone mineral density (BMD) becomes important. Also, areas such as patient

communication cannot be overlooked in this process. Each of these areas will be expanded upon in the following pages. The single most important tool in the preparation of the patient for adult spinal deformity surgery is the history and physical examination as this will be the window into each patient's unique set of risks for surgery. The history should pay special attention for any possible bleeding or thrombotic disorders—these may be related to genetic syndromes, supplement induced or related to medication that is taken for a variety of diseases.

Many adult deformity patients require extensive front back surgery from multiple approaches. The timing of these separate stages becomes important in regard to possible complications. Passias et al. compared the complication rate of front-back procedures done on the same day versus those done in a staged fashion and found a statistically significant difference favoring doing the front-back procedure in one day.³ Hassanzadeh et al. looked the timing of surgical staging and found that in patients who require both anterior and posterior surgery, staging the two procedure 21 or more days apart decreases total perioperative transfusion requirements, although significantly improving their functional outcomes versus staging the procedure by a shorter time interval.⁴

IMAGING

Depending on the practice environment in which you are working, many of your patients may present with magnetic resonance imaging (MRI) obtained prior to consultation. Because of the degenerative nature of the majority of adult spinal deformity, it is recommended to obtain and review a recent MRI in the preoperative workup. This is due to the fact that these patients have a high rate of concomitant conditions such as diffuse degenerative changes resulting in stenosis that may warrant decompression at the time of the surgical intervention aimed at the deformity. In patients who have had prior surgery with instrumentation, the MRI may be affected by metal artifact to the point of rendering it ineffective at visualization of the space available for the neural elements. The rates of repeat revision for adult spinal deformity were reported by Kelly et al. as a 21% (most commonly this was due to pseudoarthrosis, adjacent segment disease, infection and implant prominence/pain).⁵ In this setting, computed tomography myelography would likely be a better choice of the instrumented area of the spine. This allows one to take a critical look at the position of the existing instrumentation and

assess for signs of malposition, failure, or loosening. Other conditions such as the presence of magnetically activated implanted devices (pacemakers, insulin pumps, neurostimulators, cochlear implants) or metal in the brain or the eye may serve as other contraindications to MRI.

CARDIAC

Cardiac conditions are often exacerbated in the perioperative period. Avoidance of these complications can be particularly fruitful as cardiac complications have been found to be harbingers of other complications—meaning that those suffering a cardiac complication were found to be more likely to have another complication.⁶ The preoperative screening electrocardiogram (EKG) is a commonly ordered part of the workup around the time of surgery. The somewhat controversial part is whether to order an EKG in a patient without any documented or risk factors for coronary artery disease (CAD) before noncardiac surgery. The Task Force of the American Society of Anesthesiologists Practice Advisory on Preanesthesia Evaluation incorporates the integration of patient history and the surgical procedure into the decision to perform this basic test.⁷ The Task Force recognized that age alone may not be an indication for an EKG, but that there is not enough evidence to make a more definitive recommendation. The EKG is indicated without question in the setting of known cardiovascular disease or identified risk factors. Depending on the extent of the cardiac history and also on the findings of the EKG, further cardiac workup may be recommended. This generally means either a stress test, an imaging procedure such as a radionuclide scan or echocardiogram, or a cardiac catheterization. The direction of this testing would be under the supervision of the cardiologist or the anesthesiologist. If an EKG is obtained in a patient without document risk, then that information would rarely, if ever lead to decision to perform coronary revascularization. However, it may lead to the initiation or alteration of medical therapy for patients with occult disease.⁸ It is worth pointing out that any significant findings should be fully investigated and possibly addressed prior to elective surgery.

Many patients will not have a specific pathology that is amenable to procedural intervention, but they may benefit from perioperative beta-blocker therapy. The majority of ischemic complications take place the first week after surgery and are thought to be a result of an exaggerated sympathetic response that occurs perioperatively.⁹ Initiation of beta-blocker therapy should be considered in

patients who have both significant risk factors such as cerebrovascular disease, diabetes requiring insulin, chronic renal insufficiency, and CAD; and also for patients with two or more of the following: hypertension, elevated low-density lipoprotein cholesterol >240, positive smoking status, >64 years old, and diabetes not requiring insulin.^{10,11} The largest trial to evaluate the use of beta-blockers for reduction in cardiac complications is the POISE trial.¹² They looked at over 8,000 patients with CAD or at risk of CAD and assigned them to extended release metoprolol versus placebo. They found that the metoprolol group had a lower rate of myocardial infarction; however, significantly more deaths occurred in this group due to a higher incidence of stroke. The flaw in the trial was the use of extended release metoprolol, which cannot be titrated to heart rate given its long half-life. After that trial, the American College of Cardiology and the American Heart Association recommended beta-blocker therapy titrated to heart rate and blood pressure.¹³ The evidence as it relates to orthopedics specifically is not large. Urban et al. looked at 107 patients with ischemic heart disease undergoing elective total knee arthroplasty.¹⁴ They were randomized to either an esmolol drip titrated to a HR <80, then transferred over to oral metoprolol versus physician directed hemodynamic control. The incidence of myocardial ischemia was not significantly different; though there was more ischemic time in the control group.

The fact that there is a good chance that the patient will need a blood transfusion either intraoperatively or in the perioperative period should be discussed ahead of time as some patients have religious or other objections to receiving blood. In certain instances, this may preclude them from surgery.

PULMONARY

Pulmonary complications are not uncommon in the perioperative period and include entities such as atelectasis, bronchospasm, pneumonia, prolonged mechanical ventilation, exacerbation of underlying pulmonary disease, and respiratory failure. The factors that are primarily correlated with increased risk are patient age, general health status, and chronic obstructive pulmonary disease (COPD).¹⁵ These should be considered during the preoperative evaluation. In regard to “general health status,” this is evaluated preoperatively by the anesthesiologist using the American Society of Anesthesiologists (ASA) physical status classification. The ASA was created to correlate with

overall mortality risk, but it has been shown to predict pulmonary and cardiovascular complications as well.¹⁶

ASA Classification

ASA I	Normal healthy patients
ASA II	Patients with mild systemic disease
ASA III	Patients with severe systemic disease that is limiting but not incapacitating
ASA IV	Patients with incapacitating disease which is a constant threat to life
ASA V	Moribund patients not expected to live more than 24 hours
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes

The chest X-Ray is routinely obtained as part of the preoperative workup. There does not appear to be evidence to support routine ordering of a chest radiograph in a patient without history based on physical examination findings relating to pathology of the chest. Routine chest radiography may result in more misleading than helpful results.¹⁷ The abandonment of routine use of chest radiography was examined in a group of 3866 patients, of which 28% had chest X-rays ordered preoperatively based on an institutional protocol. Of the rest, there was no complication that could be linked to lack of a chest X-ray.¹⁸ In patients with documented lung disease, a chest radiograph is indicated and further workup may be needed. It should be noted that both COPD and bronchial asthma are risk factors for osteoporosis; these patients are often treated with inhaled or oral steroids, which can contribute to bone loss. Associations between pulmonary disease and decreased BMD have been documented in the literature.^{19,20} A study conducted on a healthy population, however, found no association between lung function and bone mass after adjusting for body size and other confounders.²¹ The presence of COPD is associated with an increase in pulmonary complications in the setting of any surgical procedure.¹⁵ The other common preoperative pulmonary question relates to whether pulmonary function testing (PFT) is needed. It appears that unless the patient is undergoing a lung resection—then PFTs have not been shown to predict risk more accurately than clinical evaluation.²² It is notable that these tests are often ordered in the pediatric scoliosis patient, though this is often an academic exercise. Weinstein et al. did show a correlation between right thoracic curve magnitude and decreased pulmonary function, though this is not generally clinically relevant until the curve reaches 100°. ²³ In the adult

population, there is a greater incidence of comorbidities that may indicate the ordering of PFTs, but it generally is not the scoliosis itself.

The role of smoking as a general health risk is well known and extensively documented. It may be the greatest modifiable risk factor that we face. There are numerous studies that have linked smoking specifically to deleterious findings of various sorts in spine surgery. The American College of Surgeons National Surgical Quality Improvement database looked at 14,500 adults undergoing spine surgery and divided them into active, prior, or never smokers.²⁴ The prior smokers were significantly more likely to have prolonged hospitalization compared with the never smokers. Active smokers with >60 pack years were more likely to die within 30 days of surgery. Perhaps most concerning is the association between smoking and the inhibition of lumbar spinal fusion.²⁵ Silcox et al. in an animal model established a direct link between nonunion and the presence of systemic nicotine, and found that the bone that formed when nicotine was present was biomechanically inferior.²⁵ Smoking has been documented as an indicator of unfavorable outcomes in lumbar fusion for chronic low back pain patients, a predictor of poorer outcomes in lumbar spinal stenosis patients, and a predictor of inferior results after lumbar discectomy.²⁶⁻²⁸ Smoking has been documented as a risk factor for the development of pneumonia in the postoperative period in a variety of surgical cases.²⁹ Encouragingly, Glassman et al. showed that postoperative smoking cessation helps to reverse the impact of cigarette smoking on outcomes after spinal fusion.³⁰ They found nonunion rates of 14%, 17% and 27%, respectively, for nonsmoking, those who quit for longer than 6 months after surgery, and for those that continued to smoke. Because of these factors, most surgeons will require that a patient stop smoking and discontinue the use of other forms of tobacco prior to surgery.

In the postoperative period, the most important strategies for pulmonary function optimization are lung expansion and pain management. A meta-analysis of 14 randomized controlled trials of lung expansion maneuvers found that incentive spirometry and deep breathing exercises each reduced the risk of postoperative pulmonary complications by about 50%.³¹ Continuous positive airway pressure is also an effective strategy in patients who cannot cooperate with effort-dependent modalities.³¹

The most feared perioperative pulmonary condition is likely the development of pulmonary embolic disease. In a patient who would be considered high risk for deep

vein thrombosis (DVT) or pulmonary embolism (PE) in the perioperative period, consideration should be given to the placement of an inferior vena cava (IVC) filter preoperatively. There does not appear to be any level I evidence regarding the use of chemoprophylaxis in spine surgery. McClendon et al. looked at patients that they considered high risk (criteria included a history of DVT/PE, hypercoagulability, prolonged immobilization, staged procedures of longer than five segment levels, combined anterior-posterior approaches, ilio caval manipulation during exposure, and anesthetic time of >8 hours) and found that prophylactic IVC filter placement lowered venous thromboembolism-related events, including PE development versus population controls, and was a safe procedure with two IVC filter complications in 219 patients.³² The rate of PE in a group of spine patients with similar high risk criteria has been reported at 13.1%.³³ In the postoperative period, there should be a low threshold for ordering a computed tomogram—PE protocol to evaluate for PE if the clinical situation is suspicious. Epstein et al. found the incidence of positive computed tomography angiography-PE protocols despite negative Doppler studies to be 6.7% following cervical laminectomies/fusion and 3.6% after lumbar laminectomies/noninstrumented fusion.³⁴

■ COMMUNICATION/PSYCHIATRIC/ SOCIAL ISSUES

Informed consent is a standard part of the preoperative process. This is ideally done in the physician's office prior to the scheduled day of surgery. The International Spine Study Group looked specifically into patient's ability to recall the risks that were discussed with them. If a patient experiences a complication, they might state that they were not informed of the risks because they are unable to recall the risks. The conclusions of the study were that patients feel that the informed consent process is important, but that their ability to recall risks is poor (immediate was 41%) and worsens with time.³⁵ In this study, a 20-minute video was used to reinforce the risks of surgery. It highlights the difficulties in communication faced by physicians and patients. Less than ideal communication can result in unrealistic expectations from the surgical procedure. Communication affects each aspect of the process from the consultation in the office to the postoperative care. Davis et al. examined the experience of patients undergoing spinal surgery and identified nine main

“needs” that were important to patients. These included the need for reduced waiting times, for better information and preparation, to speak up and ask questions, to feel safe, to be proactive, to be treated with dignity and respect, and the need for ongoing support, human contact, and continuity of care.³⁶ It is important to understand that the demands on a patient who is going to be undergoing a large spinal deformity surgery, or any spinal surgery for that matter, can be very psychologically taxing. Many of these patients bring to the table a history of psychiatric problems. Polatin et al. reported that 59% of patients with chronic low back pain had concurrent depressive disorder.³⁷ Interestingly, 55% of them had depression before the onset of the pain, and 45% after the development of pain. It has been reported that the psychological status strongly influences patient reported satisfaction rating.³⁸ There appears to be a correlation between a patient having depression preoperatively and that affecting outcomes postoperatively—with multiple studies reporting poorer outcomes in patients with psychiatric disease.^{39,40} Work by Adogwa et al. suggests that, the extent of preoperative depression, independent of the surgical effectiveness, influences the reported patient satisfaction after revision lumbar surgery.⁴¹ It is thought that psychological distress deteriorates the subjective outcome of lumbosacral spine fusion and psychological screening should be an integral part of the global assessment of patients preoperatively.⁴² An important corollary to the patient with psychiatric disease is the fact that many patients with psychiatric disease will be on medications that rely on a certain blood concentration in order to be effective. In the event of a large surgery with a resulting large blood loss, there can be a drop of medication to subtherapeutic levels—which can result in the potentiating of psychotic symptoms. This has been described specifically regarding lithium, which can only be given orally—therefore taking several days to return the patient to baseline levels.⁴³ Anticipation of this situation can allow for consultation with the treating psychiatrist regarding possible drug substitutions.

The patient’s social and/or psychiatric situation may be complex. It has been found that degenerative spine disease patients with more social support and less life stress tend to have greater satisfaction in medical outcomes and overall quality of life following spinal decompression surgery compared to those who have more life stress and less social support.⁴⁴ Some adult spinal deformity patients will be in a worker’s compensation situation. Workers compensation appears to have a clear, negative influence on

outcome when compared to controls.⁴⁵ Disability compensation status, however, does not seem to have the same deleterious effect on outcomes.

NUTRITION

Nutritional status is generally recognized as a key marker of overall health and its role in successful surgical outcomes is gaining attention. Various markers can be used to gauge the nutritional level of the patients. In order to quantify a patient’s nutritional status prior to surgery—generally the albumin, prealbumin, transferrin, and total lymphocyte count or any combination of these can be examined. Unfortunately, it has been shown that a high rate of surgical patients are nutritionally depleted; this is especially true for patients of advanced age.⁴⁶ This state of nutritional need leads to immune-compromise, apathy, impaired cardiac function, reduced power, and muscle wasting.⁴⁷ These changes serve as a setup for postoperative complications and failure to thrive postoperatively.⁴⁸ It has been found that the spine surgery patients most likely to be nutritionally depleted were those that: had chronic disease, spinal cord injury, osteomyelitis, or were age 60 or greater.⁴⁹

Albumin is a protein found in the blood that correlates with overall nutritional status. It has been found that low levels of serum albumin (and also elevated BUN > 30) correlated with postoperative pulmonary problems.⁵⁰ Serum albumin of 3.5 or less was found to increase the risk of mortality, complications, wound infection, and thromboembolic disease in a series of 5,887 spinal arthrodesis patients who were evaluated from data in the National Surgical Quality Improvement Program.⁵¹

Vitamin D plays a critical role in establishing optimal bone health, which is essential for a fusion to occur. The prevalence of inadequacy in the United States has been estimated at >50% in general medicine inpatients and greater than one-third of healthy young adults.⁵² The prevalence of hypovitaminosis D in an adult orthopedic surgery population was examined in a population of 723 patients and found to be 43%.⁵³ The rates of either vitamin D inadequacy (defined as a blood level <30 ng/mL) and deficiency (<20 ng/mL) were found to be 57% and 27%, respectively, in a series of 313 patients who were undergoing spinal fusion.⁵⁴ Supplementation with vitamin D3 and calcium has been found to reduce the risk of hip fractures in elderly women, indicating that dietary supplementation is an effective intervention.⁵⁵

Based on the above studies, if preoperative testing reveals a patient is not nutritionally replete, that is an indication for supplementation. The correction of the malnourished state can be a problematic task. Strategies include early mobilization, increased consumption of calories and protein-loaded foods, nasogastric or parenteral feeds, and physiotherapy.⁵⁶ A consult with the nutritionist can be helpful. Total parenteral nutrition has been found to be helpful in the setting of staged spinal surgery patients, and it correlates with a decrease in the rates of infection.⁵⁷ Total parenteral nutrition is fraught with its own set of complications, so enteral feeding routes are preferred if possible.⁵⁸

Also deserving of mention is the patient with diabetes mellitus (DM). Diabetes mellitus is known as an important risk factor for surgical site infection in spine surgery, as DM results in an immune-compromised state—with poor polymorphonuclear function, reduced wound healing potential, and poor microvascularization.⁵⁹ Satake et al. found that proteinuria was a significant predisposing factor for surgical site infection and that these patients suffer latent nephropathy.⁶⁰ They recommended consideration of less invasive techniques in this population whenever possible. Patients can be expected to have decreased complication rates if their blood glucose is tightly controlled perioperatively.⁴³ This may require utilization of an insulin sliding scale or possibly a consult from the endocrinology service to assist in managing this challenging problem.

The other common dysfunctional nutritional state encountered is obesity. It has been documented that morbid obesity increases the risks/complications, especially for patients undergoing anterior cervical or posterior lumbar operation.⁶¹ The risks associated with obesity are multiple and include an increased risk of thromboembolic disease, problems with positioning, trouble obtaining adequate localizing films, increased incidence of wrong level surgery, increased estimated blood loss, higher rate of infection, and increased perioperative wound complications.⁶² In light of these possible complications, physicians may consider various weight reduction strategies such as dieting under physician supervision and bariatric surgery. Bariatric surgery has its own set of risks and can actually lead to malabsorptive symptoms, which can in turn lead to a decrease in BMD.

■ BONE MINERAL DENSITY

Adult spinal deformity surgery is generally performed on a population with an advanced age. This is the same

population that is generally subject to decreasing BMD and osteoporosis. Osteoporosis results in a decrease in the density and the quality of bone—which leads to an increased risk of fracture. This is a widespread problem, with an estimated 10 million Americans over the age of 50 with osteoporosis.⁶³ Chin et al. looked specifically at the incidence of osteoporosis in 1,321 patients requiring spine surgery—they found a rate of 14.5% in males over the age of 50, and a rate of 51.3% in females over the same age.⁶⁴ The assessment of the patient's BMD is a vital preoperative consideration. This assessment is accomplished via dual-energy radiograph absorptiometry (DEXA) scanning. The interpretation of these scans is based on the World Health Organizations definition for osteoporosis. The number that represents osteoporosis is a DEXA T score of ≤ 2.5 , meaning >2.5 standard deviations from the BMD of a woman at her peak BMD.⁶⁵ It is important to note that the presence of an osteoporotic fracture also grants the diagnosis of osteoporosis. Many risk factors for osteoporosis have been identified and include female sex, Asiatic and Caucasian races, old age, family history, low body weight, premature menopause, nulliparity, prolonged lactation, prolonged amenorrhea, inadequate consumption of a diet containing calcium and vitamin D, poor absorption of calcium, lactose intolerance, excessive caffeine and/or alcohol consumption, smoking, sedentary lifestyle, and prolonged treatment with thyroid hormones, glucocorticoids, anticonvulsants, aluminum antacids, and anticoagulants.⁶⁶ This list of risk factors may help the surgeon preoperatively in indicating a patient for a DEXA evaluation. These risk factors also account for possible areas of optimization of the patient perioperatively. If the cause for osteoporosis, e.g. is the result of alcoholism or smoking, then the patient may see an improvement in BMD if the alcohol and smoking are removed. Approximately 95% of the time the osteoporosis is considered primary and is related to a genetic predisposition and factors that are not modifiable, including advanced age, poor health, comorbidities, and genetic predisposition.⁴³ Osteoporosis is a risk factor for failure of instrumentation and for postoperative sacral fracture at the base of a fusion construct.⁶⁷

Current medical treatment of osteoporosis is useful, in that they can maintain even increase bone mass, but generally cannot get bone mass numbers back to normal levels.⁶⁸ Current treatment generally consists of bisphosphonates, calcitonin, estrogen, selective estrogen receptor modulators, and recombinant parathyroid hormone (PTH). The newer, anabolic agent is PTH. Intermittent PTH

administration results in an anabolic effect via the direct activation of osteoblast cell surface receptors. The value of preoperative treatment of osteoporosis with antiresorptive agents in improving rates of arthrodesis and reducing rates of instrumentation failure has not been demonstrated. Much has been published on bisphosphonates and their role in bone formation. It has been demonstrated that alendronate can positively affect the process of spinal fusion in rabbits at low doses, but has an inhibitory effect at higher doses.⁶⁹ This information is of key importance as somewhere between 10% and 35% of spine fusion procedures result in pseudarthrosis, making it the most frequently encountered complication of the procedure.⁷⁰ The complex biology of spinal fusion necessitates *de novo* bone formation and remodeling by the osteoblast/osteoclast complex. This complex is selectively targeted by osteoporosis medication, which is why these drugs are investigated thoroughly with regard to spinal fusion. Hirsch et al. looked at the literature and found that existing animal data on the effect of bisphosphonate medications is conflicting but indicates that treatment delays remodeling of the fusion mass.⁷¹ The single human study suggests improvement in radiographic parameters but contains limited clinical outcome data.⁷² In regard to PTH, though no trials in humans have been performed, the current animal literature provides evidence for a beneficial effects in terms of fusion. They recommended continuation of these therapies in patients based on their indication for osteoporosis without regard to recent or future need for a spinal fusion procedure.⁷¹

The presence of decreased BMD preoperatively may alter the surgical strategy. The surgeon may opt for techniques that limit the need for internal fixation in osteoporotic bone such as minimally invasive techniques in less severe cases. Some have advocated for prophylactic vertebroplasty to attempt to prevent either compression fractures at the top of the construct or to prevent screw cut out from the top. Pneumatics et al. reported on a cadaver experiment where they compared the effect of vertebroplasty on the compressive strength of vertebral bodies and found that the failure load for the vertebroplasty specimen was not statistically significant from the nonvertebroplasty specimens.⁷³ Lotz et al. showed that cement augmentation of pedicle screw fixation in the lumbar spine could improve pull out strength by an average of 68%.⁷⁴ Other techniques that may be applied in the osteoporotic setting include sublaminar fixation, utilizing multiple points of fixation, or circumferential fusion.

PAIN MANAGEMENT

It is not atypical for the spine patient to present on a large amount of narcotic pain medication in addition to any variety of muscle relaxants, benzodiazepines, anxiety and depression medications, and neuropathic pain medications. Many of these medications have the potential for withdrawal syndromes; some of which can be dangerous, and some of which can be deadly. In a patient with an extensive medication list, it can be helpful to consult with a pain pharmacist in order to determine the narcotic equivalents the patient is currently receiving and how to adjust that in the postoperative period. This will also help safeguard that the patient does not go into withdrawal postoperatively. Generally having the patient do a complete opioid detox prior to surgery is not a reasonable course. The pharmacist can also double-check which medications may need to be stopped prior to surgery. It is well recognized that various medications such as aspirin, dipyridamole, and clopidogrel increase bleeding risk during surgery and should be stopped prior to surgery. What is likely less appreciated is the increased hypocoagulation that is seen with other commonly used substances, specifically vitamin E containing compounds (multivitamins and nuts), glucosamine and chondroitin sulfate, ginkgo biloba, fish oils, and omega-3 fatty acids.^{75,62} All of these should be stopped prior to surgery.

In addition to the pharmacy provided pain control modalities, patients who have an implanted pain pump will also be encountered. These pumps have two major concerns: the first is concerning the dosage of opioid equivalents that they are accounting for and the second is the fact that they may be in the operative field if they are intrathecally placed. If a patient is in need of a decompression at the level where the pump is implanted, the catheter may need to be removed intraoperatively to facilitate access for decompression or it may be accidentally pulled out of its position as it may physically be in the way. In the event that it is removed, it will likely be necessary to repair the dura where the pump was inserted and also to tie off the pump so it does not continue to deliver medication. In the event that the pump is an intrathecal baclofen pump, cessation of baclofen can result in a potentially life-threatening condition.⁷⁶

It is important to confer with the patient's pain management specialists prior to surgery to establish a pain plan and also to keep the pain team involved after surgery to assist in titration of the narcotic in the acute setting as well as for the long term.

INFECTION

Infection prevention strategies for adult spinal deformity patients are variable and have not specifically been reported, though we have alluded to fact that infections are often the downstream effect of some form of weakness in another facet of the patient's health—such as their nutrition or their pulmonary function. The risk of postoperative spinal infections varies from 0.4% to 3.5%—but may be reduced with a variety of measures.⁷⁷ Pediatric spinal infection prevention was investigated via a survey of 277 pediatric spine surgeons. They found that there was significant variability in current practices. This included differences in the preoperative laboratory stratification, methicillin-resistant *Staphylococcus aureus* swabs, urine cultures, IV antibiotic coverage, use of vancomycin powder, and the use of other measure such as drains and negative pressure ventilation. It was notable that 50% of surgeons attempted home chlorhexidine use prior to surgery.⁷⁸ Unplanned hospital readmissions after spine surgeries were investigated by Schairer et al. They found a single center unplanned hospital readmission rate of 8.4% at 30 days and 12.3% at 90 days.⁷⁹ Patients with longer fusions were more likely to be readmitted. Infections accounted for 45.6% of the readmissions. Given the stress on the patient, physician, and system caused by infection, it is important to do everything possible to prevent it from occurring. Most measures have been targeted toward methicillin-resistant *Staphylococcus aureus* specifically and include measures such as nasal cultures and nasally administered mupirocin, washing with chlorhexidine gluconate 4%, the routine administration of perioperative antibiotics, copious intraoperative irrigation, instrumentation coated with antibiotics, and possibly the use of various measures to apply antibiotics topically (such as a silver impregnated dressing). The question of which of the commonly available skin preparation to use has been investigated by Savage et al, who looked at 100 lumbar spine surgery patients with CholaPrep and DuraPrep—they found that both provided comparable skin prophylaxis.⁸⁰

CONCLUSION

Preoperative planning is an important component of the process of surgical management of spinal deformity. Preoperative planning includes mapping surgical techniques and planning to ensure adequate correction of deformity. Equally important is preparing the patient medically for surgery. It is easy for the spine surgeon to focus on

creating a surgical plan for the patient, but it is paramount that the patient's medical condition and physiology be considered when developing a perioperative strategy. Each of the areas discussed above represent areas of potential optimization, which translates into a smoother operative and postoperative course and creates the situation what allows your patient to maximize their outcome potential. On the flipside, these other considerations are important because they serve as areas that if not considered can result in possibly catastrophic consequences. While it is not possible to avoid complications in adult deformity surgery completely, there are many complications that may be limited with preoperative recognition and perioperative management.

The presentation of idiopathic scoliosis later in adulthood is commonly seen in spine practices. There are various reasons patients do not seek surgical treatment for their deformities earlier in life which include concerns over the safety of surgery, prior completed treatments with braces or other nonsurgical means, minor deformities that patient may be unaware of their existence, or not being overly concerned with their deformity at that stage of their life. While the majority of spinal deformities patients present as adolescents, many patients will present later in life due to persistent or progression of these deformities and concerns over appearance, weakness, radiculopathies, and axial back-related pains.

This chapter will discuss the natural history, clinical presentation, surgical planning, surgical controversies, and surgical techniques used to treat adult thoracolumbar idiopathic scoliosis.

NATURAL HISTORY

Surgeons should possess an in-depth understanding of the natural history of idiopathic scoliosis in order to provide the most beneficial treatment to the patient. Understanding the effect of time on the magnitude of the curve, the incidence and severity of back pain and concomitant stenosis, and the effect of the deformity on other organs is important in accurately counseling patients on appropriate treatments for their deformities.

Natural History of Curve Progression

Using data obtained of 133 curves in 102 patients over a span of 40 years, Weinstein and Ponseti published a longitudinal study on idiopathic curve patterns that revealed a significant general progression after skeletal maturity in 68% of curves.^{1,2} The spinal deformities that did not progress significantly measured $<30^\circ$ at skeletal maturity, irrespective of the curve pattern.^{1,2} In assessing thoracic, lumbar, and thoracolumbar curves, curves that measured 50° – 75° at skeletal maturity progressed the greatest compared to other curve intervals.^{1,2} Thoracic curves between 50° and 75° at maturity progressed a mean of 29.4° over this time interval; lumbar curves progressed a mean of 18.5° , and thoracolumbar curves progressed a mean of 22.3° .^{1,2} Prognostic factors for curve progression factors were also identified, but these findings may be somewhat limited due to the small study sample used, as only 10 adult patients with thoracolumbar idiopathic scoliosis were studied.¹ Nevertheless, Weinstein and Ponseti's study provided a benchmark for quantitatively understanding and predicting the progression of adolescent idiopathic scoliosis into adulthood.

Natural History of Back Pain in Scoliosis Patients

The presentation of axial back pain in adult scoliotic patients is common, but highly subjective in nature.³ Back

pain is diverse in etiology,⁴ and may be a result of spinal stenosis or degenerative discs or facets; however, patients with scoliosis are more predisposed to degenerative disc and rotatory listhesis and secondary stenosis as a consequence of their deformity. Kostuik reported an increased incidence of severe back pain in patients with lumbar curves $>45^\circ$.⁵ Jackson et al. further demonstrated a higher incidence of back pain and an increase in persistent back pain in patients with scoliosis.⁶ This back pain was associated with increased age and greater curve magnitude. Interestingly, in this series, the patients treated surgically had an overall reduction in spinal pain. Nachemson showed no increase in incidence of young adult scoliosis patients on disability when looking at a series of patients with a mean age of 23 years.⁷ However, in the subgroup analysis, the presence of rotatory listhesis was higher with increasing age and more common in patients with lumbar curves. Furthermore, increased curve magnitude and increased age were associated with a higher incidence of back pain.

Effect of Scoliosis on Other Organs

The effect of scoliosis on pulmonary function following maturity is not well known. Authors have demonstrated a decreasing forced vital capacity (FVC) with increasing curve magnitude.^{8,9} In this group, the FVC in patients with curves $>70^\circ$ was below the national threshold. Older reviews demonstrated a higher mortality rate, up to twice the national average, in long-term follow-up of patients with severe spinal deformities.¹⁰ In clinical practice, we rarely encounter patients with medium to large curves with clinically significant organ dysfunction.

CLINICAL PRESENTATION

In the clinical practice, there are four common presentations seen in the assessment of adult thoracolumbar idiopathic scoliosis. Patients generally present in their early adulthood with the primary complaint of deformity, later in adulthood with established degenerative changes with or without neurological claudication, or following remote surgical treatment of scoliosis with adjacent segment degeneration, stenosis, and/or alignment issues.

Presentation in Early Adulthood

Deformity, with or without pain, is the primary reason why young adults seek assessment for scoliosis.¹¹⁻¹³ Functional limitations of living with scoliosis and the psychosocial importance of physical appearance might be factors that contribute to the patient's desire to pursue surgical assessment. The main indicator for surgery in this group is

Figs. 113.1A to D: Standing posteroanterior (A) and lateral (B) long cassette radiographs of a 39-year-old presenting with back pain and deformity secondary to a 60° left thoracolumbar scoliosis. Correction is achieved with a posterior T4 to L4 construct with satisfactory alignment in both the coronal (C) and sagittal planes (D).

the baseline degree of the deformity or progression of the curve. While some of their pain may improve from surgery, future problems associated with multilevel fusions have to be considered prior to engaging in surgical treatment.

The surgical management of idiopathic curves presenting over the age of 18 can be treated in the same manner and with the same decision making used in treating adolescent curve patterns. Further growth is no longer of concern. In cases without significant disc or facet degeneration, a similar decision process is utilized concerning level selection and surgical approach is employed (Figs. 113.1A to D).

Presentation with Established Degenerative Changes

Older patients with degenerative progression may exhibit mechanical back pain as a result of secondary changes to the discs and/or facets. Rotatory listhesis is often seen at the distal end of the curve, where the most tilted vertebra subluxes on the distal spine. Maximizing nonsurgical treatments in this setting in the form of physical therapy, massage treatments, activity modifications, injections, and medications are the main recommended treatments.¹⁴⁻¹⁶

When surgery is considered, the surgery should address both the deformity and the associated levels with symptomatic degeneration.¹⁷⁻¹⁹ Workup with appropriate imaging that includes computed tomography (CT) scan and magnetic resonance imaging (MRI) to clearly define the pathology is imperative to improving surgical outcome (Figs. 113.2A to E).

Figs. 113.2A to E: Standing posteroanterior (A) and clinical (B) of a 46-year-old woman with a right lumbar scoliosis demonstrating lateral listhesis of L2 on L3 and L3 on L4. Significant degeneration of the L4-L5 and L5-S1 levels necessitated a construct that extended from T10 to the pelvis (C). Clinical postoperative photograph (D) shows a nice cosmetic correction of the rib on pelvis deformity with a well-aligned torso, with a balanced sagittal plane (E).

Stenosis Patterns with Scoliosis

Stenosis patterns are quite typical in scoliosis. Stenosis will be more prominent on the concave side of the curve. For left convex lumbar curves with a mid-lumbar apex, stenosis will occur in the upper lumbar roots on the right; however, the lower roots will be affected by the lumbosacral fractional curve, which will be apex to the right. This will result in left-sided stenosis symptoms. The stenosis from the fractional curve is generally more prevalent than those caused by the main curve. This leads to the paradoxical symptoms of left-sided stenosis symptoms with a left-sided lumbar curve (Figs. 113.3A to K). The stenosis can involve both the subarticular region and the foramen. Patients may develop degenerative facets with an associated degenerative spondylolisthesis that can lead to bilateral stenosis as well.

Surgical treatment for this group will consist of correction of the curve and decompression of the levels with stenosis. A clear understanding of the regions of nerve compression is imperative prior to surgery. While some of the areas of stenosis will decompress with the deformity correction, others will need to be formally decompressed. Appropriate preoperative cross-sectional imaging with

MRI, CT scan, and occasionally, CT myelograms will provide the necessary imaging for appropriate planning.

Revisions

Patients previously treated surgically for scoliosis are at risk of degeneration of the remaining mobile segments.^{20,21} Patients may present with or without residual coronal and/or sagittal misalignment compounding the distal degeneration. Stenosis may or may not be present as described in the previous section. Generally, constructs ending with a laminar hook in the canal will have an added source of stenosis that may need to be addressed (Figs. 113.4A to F).

Common issues related to revisions include the patient's global alignment, the residual coronal and sagittal alignment of both the fused and nonfused segments, the number of unfused segments remaining, the presence of degeneration, and/or stenosis with or without listhesis in some or all of the remaining levels. Planning how proximal and distal to extend your construct, if and where osteotomies are required, where or if to connect to the previous construct, and the metal type and name of the previous instrumentation system, will greatly improve the flow of the revision and ensure that the appropriate equipment is available for the procedure.

Figs. 113.3A to K: Spinal stenosis in the setting of a coronal plane deformity will develop on the concave side of the curve. For example, a lumbar curve with a right convex apex at L1-L2 (D), stenosis will develop on the left concave aspect at the curve apex (B and C). Because of the main curve, a secondary fractional curve develops in the lumbosacral region with an opposite configuration to the main curve. This results in lumbosacral stenosis on the right side (E to G), which is the concave side for the lumbosacral fractional curve. Because the distal lumbar levels are more prone to stenosis secondary to smaller foramina and underlying degeneration, nerve compression most often occurs in the fractional curve. Note the wide open foramina in the lower lumbar region on the convex left (A) compared to the tight distal foramina (G) on the concave side of the fractional lumbosacral curve. For these reasons, a right lumbar degenerative scoliosis with an upper lumbar apex will most often lead to right-sided neurological symptoms of the distal lumbar roots. Standing preoperative anteroposterior (H) and lateral (I) radiographs demonstrate the deformity, which was treated with a posterior T4 to pelvis procedure with L4 to sacrum decompression and interbodies as seen on the postoperative PA (J) and lateral (K) radiographs.

Figs. 113.4A to F: A 35-year-old patient presents 22 years following a T4 to L4 Harrington fusion. Anteroposterior (A) and lateral (B) demonstrate a solid construct with a Harrington flat back deformity. Inset (C) shows advanced degeneration and stenosis at L5-S1. Middle figure (D) demonstrates a close-up lateral of the lumbosacral region. Following extension of the fusion to the sacrum and pelvis (E, F) with L4 to S1 decompressions and interbody fusions, sagittal alignment was restored.

SURGICAL PLANNING

Fusion Levels

Patients presenting with deformity without significant degenerative changes can be treated with the same fusion levels that would be considered for adolescent curves. Degenerative changes present in the region of the main deformity would be addressed with the correction of the deformity. When the degenerative changes occur outside the intended fusion levels, consideration has to be made whether or not these levels should be included in the construct. Clinical judgment, MRI and CT findings, presence of nerve compression, flexibility of the unfused segments, and the number of remaining motion segments are factors that will be considered when deciding the proximal and distal levels of the construct.

Stopping at L5 versus S1

Determining the lower instrumented level is a significant controversy in adult deformity.²² More motion segments preserved can theoretically distribute the loads through more disc levels and minimize the need for early revision of distal degeneration. However, the alignment of the remaining motion segments is a contributing factor as well, and perhaps having less perfectly aligned levels may in fact last longer than more poorly aligned segments. These judgments are still open to debate.

If multiple levels cannot be preserved, the surgeon and patient must decide whether it is feasible to stop the fusion at L5 or to extend the construct to the sacrum. Stopping at L5 will preserve one motion segment, and may facilitate fusion at the instrumented segments by allowing outlet motion through the L5–S1 level. A positive for ending the construct at L5 is that it has been associated with a lower complication rate, less blood loss, lower transfusion rates, and shorter operative times.²³ However, at 3–5 years of follow-up, 15% (4/27) of these highly selective cases showed degeneration at the L5–S1 level, with the rate increasing to, 69% of cases (18/26) at 5–20 years of follow-up.²⁴ In this series, risk factors for degeneration included sagittal vertical axis ≥ 5 cm, circumferential fusions, and longer constructs (upper instrumented vertebra of T1 to T7).

Criteria for Stopping at L5

1. Sagittally and coronally balanced patient
2. No or minimal degeneration of the L5–S1 disc and facets
3. No coronal tilt to L5
4. No previous surgery at L5–S1 (i.e. L5 laminectomy)
5. No anterior listhesis at L5–S1
6. Good bone stock with excellent fixation in L5.

Distal Fixation with Long Fusions to the Sacrum

If the above criteria cannot be met, one should consider extending the fusion to the sacrum. However, with these longer constructs, the forces at the sacrum are very large due to the longer lever-arm. This creates a large flexion moment through the sacrum that could result in sacral fracture or sacral screw pullout, plowing, or loosening. Protecting the sacral screws with further distal fixation can negate some of these forces and provide the stability required to promote fusion. Commonly utilized techniques of distal fixation include iliac wing screws, S2 iliac screws, and iliosacral screws.^{25,26}

OBTAINING FUSION

Obtaining a solid fusion in a long deformity construct extending to the sacrum presents a significant challenge. There are multiple factors involved in creating an environment to promote fusion.

Biomechanical

- Adequate fixation throughout the construct
- Balanced spine in the sagittal plane
- Balanced spine in the coronal plane
- Anterior column support at high-risk levels (L4–L5, L5–S1, levels with large disc heights)
- Consideration of the position and balance of the non-fused spine
- The patient's bone density.

Biological

- Adequate bone graft (local, autograft, allograft)
- Adequate vascularized tissue in region (muscle coverage, decorticated host bone)
- Role of bone graft adjuvants and extenders.

Surgical Approach: Anterior versus Posterior versus Combined

Several authors approach all spinal deformities through a posterior approach. The posterior approach provides for exposure of the spine at all levels, while simultaneously allowing decompression of regions of stenosis, multiple fixation options with either screws, hooks, or wires, and correction of the deformity. It is the most familiar approach of the majority of spine surgeons. Interbody support can be achieved below the conus to help facilitate release and

fusion. Furthermore, posterior-based osteotomies including the Ponte or Smith Petersen, and three column osteotomies when needed, can be performed.

The role for anterior surgery in adult scoliosis surgery is evolving. Anterior surgery can be useful as the primary approach in selected Lenke V curves in younger patients with good bone stock, well preserved distal levels, and flexible, nonstructural secondary curves. The use of direct lateral approaches can facilitate correction and fusion in smaller, flexible lumbar curves, when used with either standard posterior or minimally invasive posterior techniques to supplement fixation. As well, formal anterior lumbar interbody fusions can be done at multiple levels in the lumbar spine to provide both realignment of the sagittal and coronal planes and supplement fusion of longer posterior constructs. The morbidity of the anterior approach including denervation of the abdominal wall, potential injury to major vessels, retrograde ejaculation in males, and others must be weighed against the potential benefits in fusion rates and correction.

■ COMPLICATIONS

Common spine complications in adult scoliosis surgery include pseudarthrosis, proximal junctional failure, and infection.²⁷⁻³⁰ Medical complications can occur frequently especially in patients with other comorbidities.³¹ The complication rate in adult deformity surgery can be quite high.³²⁻³⁶ Smith et al.³⁷ in a retrospective review of 206 of 453 patients showed that patients between the ages of 65 and 85 had a mean complication rate of 71% (29% major) compared to a rate of 42% (15% major) in patients between the ages of 45 and 64, and a rate of 17% (6% major) in patients between the ages of 25 and 44. Sansur et al.,³⁸ in a review of the Scoliosis Research Society database of close to 5,000 cases, noted a 13.4% short-term complication rate, with a higher incidence noted in patients undergoing osteotomies, revisions, and combined anterior, and posterior approaches.^{33,39-42} Mok et al.⁴³ noted a 26% reoperation rate in 89 patients, and Howe et al. a revision rate of 35% in 103 patients. The rate of proximal failures has been reported up to 26%.^{33,44,45}

Despite the high complication rate, outcomes from the procedure were satisfactory with Oswestry Disability Index scores improving from 43 to 24, SF-12 PCS improving from 27 to 37, back pain improving from 6.7 to 2.6, and leg pain improving from 4.9 to 2.0 in patients over the age of 65.³⁷ The expected clinical course following the surgery must be carefully delineated in advance so that the procedure can meet or exceed the patient's expectations.

■ SURGICAL TECHNIQUE

Anterior

Stand-alone anterior constructs are indicated for the young adult with a Lenke V curve pattern. A standard thoracoabdominal approach on the convex side of the curve (generally left) is performed. The fixation should extend from a minimum of the neutral vertebra to the neutral vertebra. Discectomies are performed and it is recommended to place an interbody support to maintain normal sagittal alignment through the region of fusion. Some surgeons advocate a dual rod construct on the convexity, and combination of derotation and compression is performed to achieve correction. Leveling out of the lower instrumented vertebra in the coronal plane is important to maximize the longevity of the distal nonfused motion segments. Failure to maintain the normal sagittal alignment through the construct will lead to hyperlordosis of the nonfused levels and increased loading of the distal facets (Figs. 113.5 and 113.6).

Minimally Invasive

Direct lateral approaches have been popularized for smaller lumbar deformities. The importance of appreciating the relationship of the vessels and exiting nerves is paramount with this approach, and even more important in the presence of scoliosis. For a left lumbar, the concave right side leaves a very narrow safe zone between the exiting nerve root and the vena cava (Fig. 113.7). The angle of the disc space in relation to the proximal extent of the iliac wing needs to be considered as well with regard to the feasibility of the approach. The presence of degenerative concave endplate osteophytes can complicate the approach as well. Lastly, the relationship of the genitofemoral, lateral femoral cutaneous, obturator and femoral nerves on the psoas muscle need to be considered as they will run through the "safe zone".⁴⁶⁻⁴⁹ Preoperative planning of the particular anatomy in a given case will help in deciding whether a concave lateral approach is feasible.⁵⁰ An excellent description of the relevant anatomy of the lateral approach in adult deformity surgery is well described in papers by Mundis et al.⁵¹ and Regev et al.⁵² Adjuvants to scoliosis surgery, such as intraoperative skull and skeletal traction, may correct the curve sufficiently intraoperatively to allow for safer access to the disc spaces.

Supplemental posterior fixation is recommended to supplement the direct lateral approaches. These can be done percutaneously or open. The choice of posterior levels to be instrumented should be the same regardless whether done percutaneously or open. When extending

Figs. 113.5A and B: Lumbar preoperative (A) lateral radiographs of a 21-year-old patient who underwent an anterior scoliosis correction. Anterior convex compression led to thoracolumbar kyphosis with compensatory hyperlordosis of the remaining lumbar mobile segments. Following three column osteotomy of her fusion mass (B) the thoracolumbar kyphosis is corrected. Lumbar hyperlordosis is no longer required to maintain an upright posture.

Fig. 113.7: MRI depicting the anatomy for safe zones (SZ) around the main arteries (A), veins (V) and nerves (N) with relation to the psoas (P) for access for anterior or lateral surgery in lumbar scoliosis in a typical left lumbar curve pattern. The psoas increases in volume and in its ventral extension as it travels distally in the lumbar spine. A narrow SZ is present on the right concavity between the inferior vena cava (V) and the exiting nerve roots (N) at L1-L2, L2-L3 and L3-L4. A much safer access is present on the left side at these levels. At L4-L5, the prominent psoas abuts the major venous structures ventrally on the right, leaving access to the disc space either through the transpsoas approach or through posterior retraction of the psoas muscle.

Figs. 113.6A to D: Preoperative standing posteroanterior (A) and lateral (B) views of the patient depicted in Figure 113.5. A pedicle screw-based construct extending from T4 to L4 was performed restoring her coronal (C) and sagittal balance (D).

the fusion to the sacrum, the addition of interbody support at L5–S1 is recommended.^{53,54} The minimally invasive technique is still in evolution and long-term results and outcomes need to be better investigated to determine how and where this method fits in with the spectrum of scoliosis treatment.

Posterior

Posterior approaches are the mainstay of treatment of adult deformity. It allows easy access to the canal, the foramen, and the iliac wings. Interbody fusions and osteotomies can supplement the procedure when indicated. Pedicle screw constructs offer excellent multiplanar fixation and facilitate deformity correction in multiple planes. A large variety of implant systems are available. Titanium systems offer a variety of rod options from the softer commercially pure titanium, to the medium stiffness titanium alloy, to the stiffer cobalt chrome rods. Rod stiffness can be adjusted by increasing or decreasing the rod diameter or the implant density. Titanium-based implants can be connected to the cervical spine and offer minimal artifact with MRI imaging. Stainless steel was the system of choice in the past; however, cobalt chrome rods offer similar biomechanical properties to go along with the benefits of titanium-based systems.

Goals of Surgery

- Decompression of regions of stenosis
- Level L5 in the coronal and sagittal planes

- Sagittal balance (i.e. lumbar lordosis within 10° of the pelvic incidence)
- Improved coronal curve magnitude
- Neutral transition to unfused segments
- Stable fixation
- Biological and biomechanical environment conducive for fusion.

CORRECTION MANEUVERS

When fusing to the sacrum with pelvic fixation, it is important to ensure that the rod takeoff from the sacrum is parallel to the long axis of the patient. Connecting the rod to the pelvic fixation and the S1 screw can inadvertently result in an unwanted coronal offset that will cause coronal imbalance. Similarly, correcting the main lumbar curve without leveling off the lumbosacral fractional curve will lead to coronal imbalance to the side of the convexity. For this reason, I prefer to place the concave rod of the main curve in first. This has the benefit of compressing the convexity of the lumbosacral fractional curve, to help level off L4 and L5 in the coronal plane before correcting the main curve, which is generally more flexible. Alternatively, inter-body support in L4–5 and L5–S1 can help to level these levels prior to placing the rods. In either case, leveling L4

and L5 should be a priority prior to correcting the main curve to maintain coronal balance.

For sagittal alignment, the key is to adequately bend the rod to conform to the desired sagittal plane. For this, it is important to be familiar with the mean segmental sagittal plane angulations of the thoracic and lumbar spines.⁵⁵ The T12–L1 level is neutral with lordosis increasing each level to the sacrum. Approximately two-thirds of the normal lumbar lordosis occurs between L4 and S1. From T10 to T12 there is approximately 5° of kyphosis, assuming normal thoracic kyphosis. The rod bend should reflect this. Securing the fixation to the appropriately contoured rod will correct the deformity and provide a balanced sagittal plane, assuming the rod is stiffer than the spine. For stiffer curves, the addition of posterior column osteotomies and potentially anterior releases can provide the flexibility required to correct the deformity.

Cantilever and translational maneuvers provide powerful correction of the deformities. Derotation maneuvers are useful in younger patients; however, significant loss of fixation can occur in patients with poorer bone stock. In situ bending techniques provide strong coronal correction; however, this is often at the expense of the sagittal plane. Intraoperative traction can facilitate the correction as well^{56–58} (see Figs. 113.8A to E)

Figs. 113.8A to E: Preoperative standing posteroanterior (A) and lateral (B) radiographs of a 65-year-old lady presenting with back and leg pain secondary to her spinal deformity. Intraoperative skull-skeletal traction was used as depicted in (C) providing initial correction of the deformity. Further leveling of L4 and L5 with a posterior T4 to pelvis construct restored the coronal (D) and sagittal (E) alignment.

SUMMARY

The treatment of adult thoracolumbar scoliosis is still in evolution. Techniques are continuously undergoing refinement. Powerful posterior correction systems allow for excellent corrections, especially when combined with releasing osteotomies. Despite the improved corrections, multiple controversies persist and complications and long-term outcomes are not as good as we would like. A better understanding of the principles of sagittal alignment has helped surgeons to provide more balanced spines; however, as yet, this has not translated into lower proximal failure or higher fusion rates. Working hard to maximize nonsurgical treatment, careful selection of appropriate surgical candidates, and educating patients on the realistic expectations of surgery will help improve patient satisfaction and outcome.

INTRODUCTION

Adult lumbar degenerative scoliosis (ALDS) has been increasing in prevalence in a large part due to the rising life expectancy of the past few decades and the existing elderly population. The prevalence of ALDS is reportedly anywhere from 1% to 10% of the population with new onset deformity seen in >30% of individuals after the age of 40. This has reenergized discussion of treatment principles and treatment innovations for lumbar degenerative scoliosis.

NATURAL HISTORY

Adult degenerative scoliosis is typically diagnosed in patients older than 40 years of age. These patients do not possess a history of adolescent idiopathic scoliosis and as such, this condition is often referred to as *de novo* degenerative scoliosis. The associated deformity is generally thought to develop as a result of asymmetric degeneration of discs and facet joints, an entirely separate process from that of adolescent idiopathic scoliosis of the young and growing spine.¹⁻³

Patients with ALDS may develop significant symptoms of axial or mechanical low back pain, leg pain and neurogenic claudication, as well as spinal imbalance.^{4,5}

Generalized axial back pain may be related to muscle fatigue, facet joint arthrosis, disc degeneration, and the loss of lumbar lordosis.⁶ Neurogenic claudication or radiculopathy is often secondary to central, lateral recess, or foraminal stenosis or neural compression due to the spinal deformity.

Symptoms from spinal stenosis in ALDS are not generally relieved by forward flexion, as has been noted in those with neurogenic claudication and spinal stenosis not associated with scoliosis. Instead, symptoms of spinal stenosis in those with ALDS may be relieved by the patient sitting and supporting his trunk with both arms. This distinction is important because the prognosis and treatment of ALDS are different from those with degenerative spinal stenosis.⁷ In ALDS, nerve root compression is often caused by pedicular kinking on the concave side with nerve root stretching on the convex side. Liu et al.⁸ confirmed that the L3 and L4 roots were more commonly compressed by foraminal or extraforaminal stenosis on the concave side of the curve, whereas the L5 and S1 roots were affected by lateral recess stenosis on the convex side. The magnitude of the Cobb angle, however, has not been shown to correlate with symptom severity.^{6,10}

As with all pathology related to the spine, the decision to pursue operative treatment for ALDS is primarily based

on severity of symptoms and disability. Self-assessments of health and disability, such as Oswestry disability index (ODI) and SF-12, can be useful adjuncts in decision making in ALDS. Fu et al. found that those patients electing for operative intervention generally reported worse health and greater disability than those initially treated with conservative therapy.⁹

■ CONSERVATIVE TREATMENT

Conservative or nonoperative treatment is initiated with anti-inflammatory medications, activity modification, physiotherapy, and bracing. Conservative treatment is more often successful for small curves <20° with <2 mm of lateral subluxation. These patients typically have fewer symptoms of neurogenic claudication or back pain. The efficacy of conservative treatment, however, is not firmly supported by literature. Interventional techniques like denervation of the facet joints with medial branch radio-frequency ablation, and transforaminal root blocks have been tried with varying results.

■ INDICATIONS FOR SURGERY

Patients in whom nonoperative management has failed are considered candidates for surgical treatment. Specific indications for surgery in adult patients with degenerative lumbar scoliosis may include:

- Progressive deformity
- Progressive leg pain or other neurologic manifestations
- Functional difficulties secondary to spinal imbalance
- Cardiopulmonary compromise secondary to severe spinal deformity
- Unsatisfactory cosmetic appearance secondary to spinal deformity*
- Persistent back pain failing conservative care*

A subset of patients with ALDS is often discovered on routine physical examination and is asymptomatic and therefore requires no treatment. Only a fraction of elderly adults with scoliosis ultimately elects for surgical treatment. Glassman et al.¹¹ found that the presence or absence of medical risk factors correlates with the decision to undergo corrective surgery, with nonoperative patients likely to have more risk factors. Similar to adolescent idiopathic scoliosis curves that can progress into adulthood without treatment, ALDS curves also tend to progress 1–6°

per year. This is especially true for those patients whose curves possess Cobb angles >30°–40°, an apical rotation greater than grade II, a lateral listhesis >6 mm, and an intercrestal line through the L-5 body.¹² Birknes et al.¹³ also noted that adverse prognostic factors for curve progression include curve magnitude >30°, osteoporosis, and lateral listhesis especially at the L3 and L4 segment.¹⁴

Progression of neurologic symptoms is an indication for surgical intervention.¹² Central stenosis can be successfully decompressed using a mid-line sparing hemilaminotomy technique in patients without major lateral subluxation or sagittal plane instability. In contrast, lateral recess or foraminal stenosis decompression solely on the concave side of a lumbar scoliotic curve is often inadequate owing to either insufficient correction of deformity or iatrogenic destabilization. Rotatory listhesis in and of itself results in neural compression and is believed to be a causative factor for back pain as well as radicular symptoms. Realignment of rotatory subluxation contributes to nerve root decompression and improvement in truncal imbalance that ultimately may result in relief of leg pain.¹⁵

From a mechanical perspective, low back pain is caused at least in part by facet joint arthrosis, disc degeneration, and the loss of lumbar lordosis.⁶ In most cases, nonoperative treatment is sufficient to relieve pain and restore patients with a painful deformity to their normal activities.¹⁶ For those patients with intractable back pain despite concentrated nonoperative therapy, surgical treatment may be an option although predictive relief of low back pain has not been widely reported in the literature.¹⁷ Appropriately selected ALDS patients for surgical intervention have been shown to demonstrate significant improvement in symptoms.^{18–20}

Sagittal imbalance often leads to muscular discomfort and symptomatic axial low back pain. Consequently, in order to relieve low back pain, in addition to the other necessary surgical requirements such as stenosis decompression, restoration of sagittal balance is recommended. Meaningful neural element decompression for patients with sagittal imbalance and instability is a precarious undertaking as decompression alone may lead to further deformity or instability. Important factors to consider when contemplating surgical intervention include the length of the degenerative segment, the patient's bone mineral density, the stiffness of the curve, the degree of sagittal and coronal imbalance, and the size of the patient.^{21,22}

* One must exercise extreme caution as cosmesis and back pain in isolation are not strongly supported in the literature and have highly variable success rates.

SURGICAL PLAN

If surgery is contemplated it is done so following a discussion with the patient of the risks and benefits of surgery and a critical evaluation of the patient's true complaints and physical limitations. Most often, the goals of surgery include relief of leg and back pain and correction of deformity.

To improve patient function, two basic goals need to be attained: a thorough decompression of the involved neural elements and reestablishment of both coronal and sagittal balance.²² Silva and Lenke⁷ suggested six distinct levels of operative treatment that are available for patients with symptomatic adult degenerative scoliosis:

1. Decompression alone
2. Decompression and limited instrumented posterior spinal fusion
3. Decompression and entire lumbar curve instrumented fusion
4. Decompression with anterior and posterior spinal instrumented fusion
5. Thoracic instrumentation and fusion extension
6. Inclusion of osteotomies for specific deformities.

Studies have shown that decompression alone is associated with the lowest blood loss, the shortest hospital stay, the fewest complications, the least need for revision surgery, and an improvement in the mean ODI.^{4,14,23} Decompression alone, however, is usually not recommended because it can lead to the progression of deformity and worsening of symptoms, especially at the apex of the degenerative curve.²⁴⁻²⁶ It is usually only suitable for those patients with neurogenic claudication due to central stenosis requiring a limited decompression. Silva and Lenke⁷ emphasized that posterior decompression alone is advisable only for patients with anterior osteophyte formation, <2 mm of subluxation, reasonable sagittal and coronal balance, no axial back pain, and a curve <30°. If a limited decompression alone is found to be appropriate, great care must be taken to preserve the pars interarticularis and associated facet, removing only what is necessary for decompression. If, however, a more extensive decompression is found to be necessary and the stability of spine is compromised, arthrodesis techniques warrant consideration. Pursuable options include anterior, posterior, or combined anterior and posterior lumbar procedures.^{5,26} Determining the extent of the fusion is the most important aspect of this surgery and Simmons et al. recommended the following principles when surgical intervention is indicated:²⁷

- Instrumentation should not end at the apex of a kyphosis or a spondylolisthesis
- Any level of severe rotatory subluxation should be included in the fusion
- To balance the spine, the most horizontal vertebra should be chosen as the upper instrumented vertebra (UIV). This may not always be necessary as sometimes only the apex of the deformity is fused but the supra-adjacent disc should not be severely degenerated

Decompression and short-segmented instrumented fusion within the deformity is performed in instances where the Cobb angle is <30° or where minimal lateral listhesis of the vertebral body is present. For these patients, the instrumentation should be limited to the levels of the decompression. This type of limited fusion may help to reestablish the stability of spine for patients with iatrogenic imbalance owing to decompression. Notably, this treatment is advised in patients without significant axial back pain, symptoms related to the deformity itself, and/or move up significant coronal or sagittal imbalance.^{7,14}

Long-segmented instrumented fusion and deformity correction are appropriate for patients with a higher Cobb angle in addition to coronal and sagittal imbalance.²⁵ Decreased lumbar lordosis and poor sagittal balance have been correlated with pain and functional loss. Clinically correlating pain with the location of the curve becomes very important in terms of selecting the appropriate operative treatment. More specifically, axial back pain correlates most with L-3 and L-4 endplate angulation, loss of lumbar lordosis, thoracolumbar kyphosis, and lateral listhesis.^{6,7,15,28} For this reason, the entire lumbar curve is included in the instrumented fusion subsequent to any necessary decompression procedure when axial back pain can be associated with the spinal deformity.

Compared to short segment fusion, long segment fusion has proven better in correcting scoliotic curvatures and has provided a greater advantage in improving rotational subluxation of the apical vertebra.⁴ Decompression and long segment instrumentation may help to relieve low back pain as well as the symptoms of neurogenic claudication. Radiculopathy secondary to foraminal stenosis may be relieved indirectly by correcting the deformity itself. This is especially true of the L-3 and L-4 roots that are typically compressed by foraminal or extraforaminal zone stenosis on the concave side of the curve. Unfortunately, even with long fusions, restoration of sagittal alignment in the absence of an osteotomy may be more difficult to perform in the aged spine.^{5,29}

For patients with decompression and long segment instrumentation, determining the extent of the fusion is critical in order to prevent spinal instability and progression of deformity. There has been significant debate on the extent of proximal instrumentation. This has especially been the case in situations of higher grade deformity: Cobb angle $>30^\circ$, loss of sagittal balance with reduced lumbar lordosis, and severe curves extending into the lower thoracic zone such as T-11 or T-12. Suk et al. have suggested extending the proximal fusion to T-10 level in general due to an increased risk of proximal junctional kyphosis when fusion is only extended to the T-11 or T-12 level. The T-11 and T-12 vertebral levels have floating ribs, and therefore are not stable zones to end fixation.

Proximal fusion levels should start at the neutral and stable vertebrae, as defined by the central sacral vertical line. If the coronal plane deformity allows, the UIV should be normalized in the coronal plane, aligning the superior endplate and the adjacent disc in the horizontal plane. Theoretically, this should decrease shear forces associated with a disc space that is skewed in the coronal plane. The proximal extent of fusion should therefore allow for both restoration of the sagittal alignment within the instrumented segments and should serve as the transition to normally aligned proximal vertebral segments in the sagittal plane. Some surgeons will end the fusion above the apex of the curvature but within the curve as long as the disc above is symmetrical and not severely degenerated.

Cho et al. noted that neutral vertebrae, rather than stable vertebrae, were found most often at T-11 or T-12 in the setting of a degenerative scoliotic curve. They also noted similarly that fusion to T-10 was more reliable compared to fusion to T-11 or L-1 due to the extra stabilization the ribs offered at the thoracolumbar junction. Stopping the fusion at L-1 or L-2 resulted in the highest incidence of proximal adjacent segment disease, whereas fusion to T-10 had the lowest incidence. From a biomechanical perspective, true nonfloating ribs tend to increase the stability of the thoracic spine through the thoracic rib cage. The rib cage effectively lengthens the transverse dimensions of the spine, giving the thoracic spine greater resistance to moment forces in the sagittal, coronal, and axial planes. The upper 10 thoracic vertebrae (T-1 to T-10) obtain this mechanical support through the true ribs, but T-11 and T-12 have floating ribs without costosternal articulation. These levels lack the ligamentous support provided by the costovertebral, costocorporeal, and costotransverse articulations. Hence, stopping at or distal to the T-11 and

T-12 levels puts the adjacent segment at a biomechanical disadvantage. Interestingly Cho et al. were unable to demonstrate a significant difference in the rate of proximal adjacent segment disease with fusion to T-10 versus fusion to T-11 or T-12. They found that proximal adjacent segment disease occurred more commonly when the fusion stopped at or below the upper end vertebrae of the deformity in the coronal plane. The neutral vertebra was found to adequately represent the UIV.

Driven in part by the concern that a fusion to the sacrum can lead to subsequent degeneration of the sacroiliac joint, altered gait mechanics, and an increased pseudoarthrosis rate, the sacrum is often excluded from the fusion construct when possible. If fusion to the sacrum is indicated, a combined approach is recommended to maximize the fusion rate, reestablish lumbar lordosis, and to prevent implant failure across the lumbosacral junction. Bridwell et al. recommended only including the sacrum in the fusion construct when there exists: a spondylolisthesis at L5-S1, stenosis at L5-S1, a prior laminectomy at L5-S1, or an oblique takeoff at L5-S1. Cho recommended that a fusion should stop at L-5 when the L5-S1 disc displayed a healthy appearance on magnetic resonance imaging. He recommended extension to the sacrum only in the cases of pre-existing pathology at L5-S1, such as spondylolisthesis and spinal stenosis, or significant sagittal imbalance that in turn is more likely to lead to subsequent disc degeneration at the L5-S1 level.^{28,40}

The distal fusion level should be at a neutral and stable vertebra and should never end at a segment with a rotated spinal segment. The subadjacent segment should have little or no disc or facet degeneration. The first sacral level must be included in the distal fusion to achieve balance if there is an oblique takeoff of L5 on the sacrum with a fractional curve $>15^\circ$, a spondylolisthesis, or stenosis at the L5-S1 level.⁷

To summarize, the fusion level should not stop at a segment with a rotated spinal segment in order to avoid aggravating further subluxation in the postoperative period. In addition, to prevent issues in the adjacent segment, it is recommended that a surgeon not stop a fusion at the apex of the deformity in either the coronal or sagittal plane.²⁹ Furthermore, the thoracic physiologic kyphotic apex must be avoided as an endpoint for instrumentation as caudal instrumentation can act as a moment arm that can lead to further progression of deformity.³⁰ Finally, the surgeon should avoid ending instrumentation at a segment with posterior column deficiency or listhesis in any direction.

In general, most patients with ALDS do not require an osteotomy. Posterior lumbar interbody fusion (PLIF) and transforaminal lumbar interbody fusion (TLIF) can have a positive effect on restoring sagittal and coronal balance owing to a combination of an anterior release and the support of an intervertebral graft.²⁹ If the stiffness of the deformity is such that it cannot be corrected by an anterior release and posterior instrumentation, then partial resection of the inferior articular processes may be required. In more severe cases, spinal osteotomies such as a pedicle subtraction osteotomy or Smith-Petersen osteotomy aid clinical realignment and subsequently decrease the stresses seen at the instrumentation-bone interface.

SURGICAL TECHNIQUE

For the treatment of adult spinal deformities, the available approaches include anterior-only, posterior-only, and combined anterior and posterior surgery. Minimally invasive techniques and nonfusion techniques have also been discussed.

Anterior-only Approach

Anterior lumbar interbody fusion (ALIF) has been shown as a reliable technique in the treatment of adult spinal deformity. Studies have shown that an anterior release with structural anterior column support may provide several benefits, including improved stability, decreased stress on spinal implants, improved fusion rates, better correction of lumbar lordosis, and consequently a direct reduction in the number of fusion levels necessary. The thorough release of contracted tissues and osteophytes, preparation of the interbody space, and placement of structural anterior column support is more directly achieved from an anterior approach.³¹⁻³³

Only a few relatively young adult patients with ALDS ultimately undergo an anterior-only approach. Pain from the anterior incision, incisional hernia, ileus, abdominal adhesions and strictures, large vessel injury, and other complications have been associated with the anterior approach.³⁴ The anterior only technique is not typically used in older osteoporotic patients secondary to the increased risk of catastrophic anterior instrumentation failure. An ALIF is therefore usually combined with a posterior instrumented correction and fusion. Various studies, however, have found that deformity correction is not consistently improved with the addition of anterior surgery in degenerative lumbar scoliosis.^{33,35,36} Crandall et al.³⁵ compared

the clinical and radiographic outcomes in degenerative lumbar scoliosis patients treated with posterior-instrumented correction and fusion combined with ALIF to TLIF. They found that both ALIF and TLIF are effective in improving clinical and radiographic results in degenerative lumbar scoliosis patients. They also noted that deformity correction was similar (70%) between the two groups. Ultimately, the authors concluded that anterior surgery is not routinely required to treat all cases of degenerative lumbar scoliosis.

Posterior-only Approaches

Nowadays, more and more surgeons prefer to perform a posterior-only approach for ALDS patients. In general, most patients with lumbar degenerative scoliosis also have concomitant spinal stenosis secondary to degeneration, and thus, these patients often require a direct posterior decompression.^{31,32} Growing evidence suggests that a posterior-only approach may be as effective as combined anterior-posterior surgery for most cases.^{39,40} Aggressive decompression alone, however, may be a detriment to the stability of spine and result in curve progression.^{22,37} The use of posteriorly placed interbody grafts in deformity correction surgery has gained popularity as a means of providing anterior column structural stability, increased fusion rates, and restoring as well as preserving lumbar lordosis.^{31,36,38} Biomechanical analysis has demonstrated that the use of TLIF grafts and bilateral pedicle screws allow deformity correction with restoration of the mechanical stiffness of spine 10–20% greater than that of non-instrumented specimens.⁴¹ Despite minor biomechanical differences between TLIF and ALIF stiffness, both procedures significantly enhance segmental stability with good clinical results.^{35,36,42}

Special Surgical Technique

Less Invasive Surgical Correction

Traditionally, the interbody fusion graft is placed through either an anterior (ALIF) or posterior (PLIF or TLIF) approach. Posterior approaches (PLIF and TLIF) place the nerve roots and thecal sac at greater risk during graft insertion because these structures must necessarily be exposed, and then protected. With the advance of surgical technique, more and more procedures like these may be performed by minimally invasive means. Minimally invasive surgery is still in its relative infancy and the majority

of the touted advantages are somewhat theoretical at this point and not clearly supported in the literature. The proposed advantages include decreased blood loss, shorter operating time, less postoperative pain, lower risk to the neural elements, shorter hospital stay, and faster return to activities. This “evidence” has supported the growing usage of minimally invasive techniques in spine surgery.

Among spinal deformity surgeries, adult deformity corrective procedures carry a higher complication rate, because this group often has multiple comorbidities.^{43,44} For ALDS patients, minimally invasive surgery may include posterior multilevel percutaneous pedicle instrumentation and one or a combination of the following interbody disc release and fusion procedures: Lateral interbody fusion and axial lumbar interbody fusion (AxiaLIF). The lateral approach provides an alternative to traditional interbody approaches, which uses a corridor that is designed to protect the vital structures both anteriorly and posteriorly to the vertebral body. With the lateral approach, access to the spine from the T-7 level down to the L4-5 level is possible. However, the L4-5 level is often difficult to reach due to a high riding iliac crest. The means to access the L5-S1 laterally has not been developed.^{45,46}

For ALDS patients, the proposed advantages of minimally invasive surgery make it a promising technique. In comparison to the more familiar posterior approach, minimally invasive lateral access to the spine is a relatively technically demanding method with a steep learning curve.

Nonfusion Technique

In elderly patients, the type of surgery chosen should be the least aggressive possible, and the length of the surgical procedure should be considered very carefully.⁴⁷ The surgical treatment of ALDS with spinal arthrodesis in addition to decompression of neural elements may require a lengthy surgery with excessive intraoperative blood loss. Operative time appears to be the most significant risk factor for early perioperative complications.⁴⁸ As alternatives to spinal arthrodesis, nonfusion-instrumented techniques such as pedicle-based dynamic instrumentation systems and soft stabilization devices have been used for the treatment of degenerative diseases. Some authors have presented promising results using the Dynesys system in the treatment of degenerative spondylolisthesis.^{49,50} Silvestre et al.⁵¹ performed nonfusion techniques after a decompressive laminectomy with the dynamic stabilization (Dynesys) system in 29 elderly patients with degenerative lumbar scoliosis. Radiographic evaluation at follow-up

revealed that the dynamic fixation system provided substantial stability. It prevented further scoliosis progression and spondylolisthesis after wide laminectomy. However, not every author has reported satisfactory results with these implants.⁵² Kanayama et al.⁵³ concluded that spinal “ligamentoplasty” cannot completely replace spinal fusion. More studies are needed to validate its use in this degenerative pathology.

RESULTS AND COMPLICATIONS

Due to the technical complexity, extensive need for spinal reconstruction and confounding patient comorbidities; surgery for adult degenerative scoliosis is associated with a relatively high rate of complications. In the overwhelming majority of cases the age of the patient is the primary risk factor for perioperative complications. This was demonstrated in a large series by Pedro Berjano et al., where the frequency of complications was directly related to the patient's age. The incidence of major complications and overall complication incidence rate was 6% and 17%, respectively, in the 25–44 age group, 15% and 42%, respectively, in the 45–64 age group, and 29% and 71%, respectively, in the >65 age group.

Clinical Results

Despite being fraught with potential complications in general, the clinical improvement of ALDS patients undergoing surgical correction is favorable. This is especially true in terms of overall pain visual analog scale (VAS) and ODI when compared to that of their preoperative status.³⁵ Interestingly, the mean ODI has not shown to significantly differ among patients who have experienced early complications with those who have not. This outcome may just be a factor of the relatively benign nature of the vast majority of early complications. In contrast, patients suffering from late complications display significant worsening of their ODI from baseline relative to those patients who did not experience late complications.

A major factor negatively affecting clinical outcome is a resultant positive sagittal imbalance.⁴⁸ Studies have demonstrated that patients with a predominant back pain component who have failed to respond to non-operative treatment can typically expect a 50% improvement in pain and function with surgical intervention.¹⁰ On the other hand, patients with radiculopathy as their primary complaint usually note a 75% improvement in leg discomfort.^{55,56}

When neurologic claudication is the primary indication for surgery, postoperative SF-36 has demonstrated a statistically significant improvement in bodily pain, social function, emotional health, mental health, and mental composite. As would be expected, patients tended to be more satisfied with the outcome of surgery if their claudication was eliminated.²⁹ Two risk factors that account for a less than successful outcome are a sacrum to curve apex fusion (i.e. short segment fusion) and a positive sagittal imbalance after surgery.⁴ Of course the extent of surgical aggressiveness is an important factor that impacts the improvement of self-assessment survey results. Improved ODI scores have been routinely seen in decompression alone and decompression with limited fusion, but not in decompression with full curve fusion.⁴ A potential reason for this discrepancy is that decompression with full curve fusion is associated with an increase in intraoperative blood loss and hospital stay relative to decompression alone.⁴

Crandall et al.³⁵ found no statistical difference between the ALIF and TLIF groups in ODI, VAS, and pain medication use. The decline in use of pain medication after surgical treatment was nearly identical between the groups. Minimally invasive interbody fusion has also been shown to improve the self-assessment survey results. TorMenti et al.⁵⁷ found that patients who underwent combined extreme lateral interbody fusion and posterior instrumentation had VAS scores that dramatically decreased when comparing preoperative (mean 8.8) to postoperative values (mean 3.5).

Radiographic Results

As mentioned before, the use of interbody grafts in deformity correction surgery may help to restore and preserve the alignment of the lumbar spine. The percent of coronal curve correction is about 70% in ALIF and TLIF patients and the difference between the two groups does not appear to reach statistical significance. The correction of the deformity, however, is not the primary goal of surgery for patients undergoing decompression only or decompression with limited fusion. Consequently, radiographic measurements of the main lumbar curve, lumbosacral curve and lumbar lordosis exist unchanged pre- and postoperatively in these patients. In contradistinction, these parameters are improved significantly when looking at patients who underwent full curve fusion, though the clinical benefit of such an extensive procedure is unclear.⁴

Complications

The spectrum of perioperative complications of ALDS can be divided into early and late complications:

- Early/perioperative complications
 - Neurologic deficit
 - Epidural hematoma
 - CSF leak
 - Wound infection
 - Urinary tract infection
 - Cardiopulmonary disease
 - Deep vein thrombosis
 - Ileus
- Late complications
 - Pseudarthrosis
 - Failure of instrumentation
 - Adjacent segment disease

Degenerative lumbar scoliosis is mostly seen in the elderly population who present with a myriad medical co-morbidities.¹² Among spinal deformity surgeries, adult deformity corrective procedures carry a high complication rate. Complications include urinary tract infection, wound infection, pseudarthrosis, hardware failure, durotomy, myocardial infarction, neurologic injury, adjacent segment degeneration, blindness, and death.^{14,43,44,54,60-62} Published potential complications for the operative treatment of adult degenerative scoliosis span the entire spectrum of severity, and vary depending on the type of operation, chosen surgical approach, and the presence or absence of instrumentation.

Cho et al.⁴⁸ reported that 14 of 49 patients developed early complications and 18 developed late complications in one small surgical study of patients with degenerative scoliosis. In a larger study, the authors reported 643 patients who underwent a posterior-only approach for degenerative scoliosis.⁴⁰ They reported only a 9% reoperation rate for pseudarthrosis (3.7%), curve progression (2.0%), infection (1.4%), and prominent instrumentation (0.6%) after a 4-year follow-up period. The incidence of complications in other series ranged from 20% to 80%.^{28,58} With advances in neurophysiologic monitoring, and improvements in perioperative management, these risks have decreased significantly.⁴³ Numerous factors are attributed to the development of complications including, but not limited to, motion segment stiffness, osteoporosis, stenosis, spondylolisthesis, rotation, instability, spinal imbalance, and medical comorbidities.^{48,59}

Early perioperative complications usually are operation or approach-related complications. One of the most

significant operative complication is excessive intraoperative blood loss, directly related to the number of levels fused.⁵⁸ Different approaches are also associated with different complications. For example, the anterior approach is associated with complications that include vascular injury, ileus, and retrograde ejaculation.⁶³ Approach-related complications of the lateral minimally invasive approach include bowel or other abdominal viscera injury, numbness, dysesthesia, and pain in the groin and lateral thigh and psoas weakness.⁴⁶

Late complications are often instrumentation related and consist of pseudarthrosis, adjacent segment disease, and implant failure among others. Fusion extending to the sacrum entails a larger operation with an increased rate of pseudarthrosis at the lumbosacral junction.⁶⁴ Kim et al.⁶¹ found an overall pseudarthrosis rate of 24%, with nearly half of those patients developing pseudarthroses at L5–S1. Risk factors for the development of pseudarthrosis include a thoracolumbar kyphosis, hip osteoarthritis, positive sagittal balance >5 cm, age >55 years, and incomplete sacropelvic fixation.^{13,61}

There is a tendency for increased adjacent segment disease following short-segment fusion compared to long-segment fusion. Cho's et al.²⁹ found that proximal adjacent segment disease was seen in all cases with short segment fusion. On the contrary, in long segment fusions, there were only two cases of proximal adjacent segment disease and three cases of distal adjacent segment disease. Despite the presence of high complication rates and difficult decision making, the clinical outcomes appear to support such risks in appropriately selected patients.¹⁹ As mentioned previously, these procedures must require careful planning and patient education to decrease the complication rate and to manage the patient's expectations.

POSTOPERATIVE MANAGEMENT

One or more antibiotics should be administered for at least 24 hours postoperatively to prevent a surgical site infection. Nutritional supplementation should be considered until patients are able to consume enough calories independently, typically occurring by the second or third postoperative day. Postoperative pain management in the immediate postoperative period is very important to expedite functional rehabilitation. This may present a challenge for patients with long-term narcotic usage. If possible, patient-controlled analgesia should be used in these patients. Due to the adverse effect on fusion rates,

nonsteroidal anti-inflammatory drugs are not recommended in fusion patients. All patients should be given full-length antiembolic compression stockings. A Vena cava filter before surgery may be considered for high-risk patients or patients with known history of deep vein thrombosis who have contraindications to blood-thinner usage.

Patients are encouraged to walk with a fitted custom thoracolumbosacral orthosis as soon as all wound drains are removed, which typically occurs by the second or third postoperative day. Patients are instructed to wear the orthosis whenever they are out of bed for at least 3 months. Full-length radiographs are taken at 3 months, 6 months, 1 year, and 2 years follow-up.

SUMMARY

Patients with ALDS may develop significant symptoms of low back pain, leg pain, and spinal imbalance. The goals of surgical treatment include relief of leg and back pain, and the correction of deformity. Transfeldt et al.⁴ noted that there are a myriad of factors to be considered when considering surgery. How much back pain is there compared to leg pain? If the primary purpose of the surgery is to relieve radiculopathy, will the patient be able to put up with their residual back pain? Would the patient prefer to have a smaller decompressive operation now and face the risk of a fusion later, or would they rather have a bigger surgery now with a less likelihood of more surgery later?

Several surgical options are available for degenerative lumbar scoliosis, including decompression alone, decompression with limited fusion within the deformity, and decompression with long segment instrumentation. However, these complex surgeries are accompanied by substantial complications mostly due to the advanced age of this patient population.¹² When considering the various complications, no statistically significant difference has been demonstrated between the ALIF and TLIF groups for rate of nonunion, adjacent fracture, adjacent level disease, infection, or other complications. The advent of minimally invasive decompression techniques has so far not led to improved outcomes for patients with lumbar deformities who wish to avoid spinal fusion.

» Types of Osteotomies

» Application of Osteotomy Procedures and Bone Union

INTRODUCTION

The goal of surgical treatment for spinal deformity is to correct the deformity and to stop the progression of abnormal spinal curvature. However, it is sometimes difficult to achieve a straight spinal column in the coronal aspect and a physiological curvature in the sagittal aspect. This can be due to overlooked disadvantages such as the loss of mobile segments from the spinal fusion and possible surgical complications from the correction of the spinal deformity. Surgeons should consider how many mobile segments must be sacrificed for adequate correction and fusion in the spinal column and attempt to fuse the shortest segment possible, with minimal complications. Occasionally, secondary curvatures (nonstructural) can be spontaneously corrected with the improved spinal balance from the correction of the main curve. However, some secondary curves may not be corrected, leading to deterioration of the spinal balance; a consequence of the correction of the main curve.

Abnormal spinal balance can cause not only progression of the residual curvatures but also reduced quality of life due to back pain, lower extremity pain, and neurological symptoms during long-term follow-up period.^{1,2} Therefore, the ultimate goal in the surgical treatment of spinal deformity is the maintenance and acquisition of not only coronal but also sagittal spinal balance with the fewest fusion segments. In some patients, surgeons may need to correct very rigid curvatures in order to achieve these goals.

The types, characteristics, and magnitude of spinal deformities vary between patients. The types of curvature

in congenital scoliosis or kyphosis may be more angular with greater rigidity. Other deformities in adult scoliosis or kyphoscoliosis may be sagittally or coronally off-balance due to degenerative changes in the lower lumbar segments. Although spinal instrumentation has progressed with increasing potential for correction, those patients with high angular rigidity and/or “take-off” in coronal or sagittal balance frequently need vertebral osteotomies for the correction of these curvatures. This chapter will describe the techniques and indications of various types of vertebral osteotomies for thoracolumbar deformities. Intraoperative spinal cord monitoring (especially motor-evoked potentials) is required in all osteotomy procedures described in this chapter as a necessary antecedent or precondition to prevent spinal cord-related neurologic complications. However, perioperative surgical complications are described in a different chapter.

TYPES OF OSTEOTOMIES

Although many spinal surgeons have introduced various types of vertebral osteotomies,³⁻⁹ they can be mainly categorized into three types: posterior chevron-shaped osteotomy, wedged-osteotomy including posterior subtraction osteotomy, and vertebral column resection (VCR).

Posterior Chevron-Shaped Osteotomy

The posterior wedged-shaped osteotomy, chevron manner, was first introduced by Smith-Petersen, et al.⁴ in 1945.

Fig. 115.1: Chevron-shaped osteotomy (Smith-Petersen osteotomy, Ponte osteotomy). Resection of bilateral superior and inferior facet joints in a chevron fashion (arrows).

It was initially employed to correct kyphosis caused by ankylosing spondylitis using this method. Several surgeons have attempted this type of osteotomy with a combined anterior and posterior approach for the iatrogenic flat back due to previous fusion,¹⁰⁻¹⁴ multiple applications for Scheuermann disease,⁴ as well as kyphosis due to ankylosing spondylitis.^{14,15} Multiple applications of *posterior chevron-shaped osteotomies* for Scheuermann diseases were first introduced by Ponte, et al. in 1984.⁹ Smith-Petersen osteotomy (SPO) and Ponte osteotomy are frequently confused and interchangeably described, although originally SPO was designed to be performed at only one segment while Ponte osteotomy is designed for multiple segments. This chapter treats both types of osteotomy as “chevron-shaped osteotomies” because they apply a similar surgical technique and procedure in terms of anatomical aspects in spite of the difference in the number of segments that are osteotomized.

Surgical Planning and Technique

This type of osteotomy may be performed with combined anterior and posterior approaches or through only a posterior approach. The chevron-shaped osteotomy is actually only performed for posterior structures, regardless of which approach is chosen. Preoperative evaluation and construction of a valid strategy for the correction of the spinal deformity are very important and surgeons should decide which and how many intervertebral segments

Fig. 115.2: Asymmetrical chevron-shaped osteotomy. Multiple asymmetrical chevron-type osteotomies were planned on the periapical segments from T7 to T12 for correction of severe scoliosis.

must be osteotomized to obtain the maximum correction of either scoliosis and/or kyphosis. Obtaining 5–10° per segment is the approximate goal for chevron-shaped osteotomy and surgeons must estimate the amount of correction of the spinal curvature required to achieve ideal coronal and sagittal balance by determining how many segments to be osteotomized in a chevron fashion.¹⁶

Initially, the bilateral inferior facets are completely resected using a rongeur or an osteotome followed by resection of the superior facets by using a Kerrison rongeur. The roots usually run medioinferior to the pedicle from the medial to lateral region. Surgeons will be required to carefully dissect the roots from the surrounding tissues. The key here is to expose the roots completely, up to the far lateral site by releasing even the intertransverse ligaments to prevent root impingement at the time of correction, which is achieved by closing the osteotomized gap (Fig. 115.1). Chevron-type osteotomy should be asymmetrically performed in patients with severe scoliosis or kyphoscoliosis, for correction of scoliosis (Figs. 115.2 and 115.3).

Typical SPO or Ponte osteotomy was originally established as a posterior closing osteotomy without any anterior release.^{4,9} The anterior longitudinal ligament acts as a hinge in SPO or Ponte osteotomy to correct kyphosis. These types of posterior chevron osteotomies may be appropriate for sagittal imbalance or kyphosis, but not for coronal deformity.¹⁷ Some surgeons modify the SPO or Ponte osteotomies through a combined anterior release and posterior approach, thus causing an anterior opening posterior closing osteotomy with the posterior longitudinal ligament acting as a hinge, or through a posterior only approach by placement of a strut bone graft or a cage as a focus for center of rotation¹⁸ (Figs. 115.4A to C).

Figs. 115.3A and B: Correction of scoliosis using multiple chevron-shaped osteotomies. Case: A 10-year-old female with early onset scoliosis. Scoliosis was corrected from 116° to 30° using multiple chevron-shaped osteotomies from T7 to T12.

Figs. 115.4A to C: Modification of chevron-type osteotomy. Local kyphosis (A) can be corrected using chevron-shaped osteotomy. Anterior release combined chevron-shaped osteotomy with a strut bone into the gap (B) can correct kyphosis much better than simple chevron-shaped osteotomy (C).

Wedge-Osteotomy

Wedge-osteotomy can be simply summarized as a wedge-shaped resection of both anterior and posterior structures on the vertebral column for the correction of three-dimensional deformities. There are two types of wedge-osteotomy based on the location of osteotomy on the vertebra: intravertebral and intervertebral. The former is an osteotomy performed inside of a single vertebra; including pedicle subtraction osteotomy (Posterior Three-Column Wedge-Resection, PSO).^{3,19-26} Transpedicular decancellation osteotomy (TDO) also belongs to this group.^{6,27-30} Pedicle subtraction osteotomy and TDO are almost the same procedure in terms of the approach through pedicles with the addition of wedged-shape resection of the lateral wall and posterior cortex of vertebral body in PSO (Figs. 115.5A and B).

Pedicle Subtraction Osteotomy

Thomasen³ first presented posterior traspedicular subtraction osteotomy for correction of kyphosis in patients with ankylosing spondylitis. This procedure is a three-column osteotomy with a wedge-shaped osteotomy inside one vertebra through a posterior approach.

Figs. 115.5A and B: Intravertebral posterior three-column wedge-resection. (A) Transpedicular decancellation osteotomy. (B) Pedicle subtraction osteotomy (posterior three-column wedge-resection).

Surgical Planning and Technique of PSO

The site of osteotomy is at the apex of the kyphosis if possible and it may be located at L2, L3, or L4 in most patients with degenerative adult lumbar kyphoscoliosis. Preoperative evaluation of parameters related to the coronal and sagittal alignment, such as flexibility of main and adjacent curves, L4 tilting angle, pelvic tilt, and pelvic incidence, is important for determining operative strategies of spinal deformities.¹⁶ Several surgeons have attempted to predict restoration of sagittal alignment after vertebral osteotomies and correction/fusion using mathematical formulas.³¹⁻³³ Most of these formulas, however, are known to be unreliable at best to predict sagittal vertical axis after vertebral osteotomies because of the influence of pelvic parameters and secondary changes of unfused curves; factors that are difficult to predict after the correction of main curves.³⁴

For procedures that destabilize the spine, pedicle screws should be inserted first. Prior to performing a PSO, pedicle screws should be inserted at least two vertebrae cranially and caudally from the target vertebra (at least four screws above and below). Fusion may be extended beyond the deformed vertebrae if old compression fractures are recognized at locations adjacent to the upper end or lower end of the instrumented vertebrae (UIV, LIV). Magnetic resonance imaging may give us useful information related to the determination of UIV or LIV.

The area of osteotomy is outlined followed by laminectomy with complete bilateral facet removal. The dural sac and the bilateral roots that run medially along the pedicle are exposed. The bilateral pedicles of the vertebra for PSO

are isolated from the surrounding tissues, first medially, then caudally, cranially, and finally, their lateral walls are exposed by resecting the transverse processes and/or the medial side of the ribs up to the tip of rib heads. The lateral wall of the vertebral body is subperiosteally exposed, and the vertebral body is removed piece by piece, through a transpedicular approach. The removal of the lateral cortex of the vertebral body should be done in a wedge-shaped fashion without damaging the periosteum. The medial wall of the pedicles can be used to protect the neural tissues during this procedure. The removal of the medial wall of the pedicles should be done after removing some of the bone from the vertebral body because the medial wall of the pedicles can be a barrier during procedures in terms of prevention of neural damage and bleeding from epidural vessels. The vertebral cortex under the dural sac should be removed after cauterization of both the epidural vessels and the longitudinal ligament at the same time. It is very dangerous to retract the dural sac at the time of removal of the dorsal cortex of the vertebral body, particularly in the thoracic area. The L-shaped bone impactor or a curette may be useful for removal of this portion. The key is to control the bleeding from the epidural vessels or basivertebral vessels during removal. A rod may have to be temporarily placed before the posterior wall of the vertebral body is removed in order to stabilize the vertebral column, preventing the gap from decreasing or displacing the cranial vertebral column from the caudal one. Correction is thus achieved by closing the osteotomized gap and using the anterior cortex as a hinge during a compression maneuver. Extra precautions must be taken to prevent the impingement of the roots and dural invagination at the

Figs. 115.6A to E: Intervertebral posterior three-column wedge-resection (extended pedicle subtraction osteotomy). (A) Laminectomy and facetectomy. (B) Pediclectomy and transpedicular wedge resection of the vertebral body. (C) Placement of the rod. (D) Strut bone graft into the gap as a furculum followed by correction of kyphosis using cantilever maneuver. (E) Correction of kyphosis by using compression maneuver with a furculum of the strut bone placed in the vertebrectomized gap.

edge of the laminae. Bridewell^{22,23} reported partial removal of laminae at the center of the spinal canal in order to check whether the neural tissues are impinged. All lamina are routinely removed to securely check that both the dural sac and nerve roots are free from compression while closing the wedge-shaped defect to correct the kyphosis. The defect between the cranial and caudal laminae should be grafted with local autograft bone to ensure bony union.

Intervertebral Wedge Osteotomy

Intervertebral wedge resection is a type of osteotomy beyond the endplates and into intervertebral discs cranial and/or caudal to the vertebra, and is commonly combined with PSO. If greater correction of kyphosis is required, resection of the disc cranial to the osteotomized vertebra in addition to the PSO procedure may be done to obtain a greater correction angle (Figs. 115.6A to E). This may be called an “extended pedicle subtraction osteotomy (EPSO)” (Figs. 115.7A to C).

Intervertebral wedge osteotomy through an anterior and posterior combined approach may be useful for the correction of hyperlordosis of the lumbar spine or segmentation failure of congenital scoliosis. Lewis et al.³⁵ reported anterior vertebral wedge osteotomy with resection of disc tissue combined with a posterior SPO for the correction of a fixed lumbar hyperlordosis. However, they failed to correct hyperlordosis using simple posterior distraction

because the anterior osteotomized gap also opened at the same time. Consequently, they achieved correction of hyperlordosis through posterior reduction to an under-contoured rod. They named this procedure “Reverse Smith-Petersen Osteotomy (RSPO)”. Wang et al.³⁶ presented the case of one patient with arthrogryposis exhibiting severe hyperlordosis that was corrected by bending the operating table after anterior wedge osteotomy and posterior SPO. Correction of a fixed lumbar hyperlordosis requires a combined anterior wedge resection and posterior SPO followed by an anterior shortening and posterior lengthening procedure.

Segmentation failure in congenital scoliosis may be another proper candidate for combined anterior wedge osteotomy and posterior asymmetrical chevron-shaped osteotomy. These deformities often include anomalies in multiple segments. It is much safer and easier to perform intervertebral release and wedge resection of the anomalous vertebral segments both cranially and caudally in order to change wedged vertebral bodies into a rectangular shape through the anterior approach. In addition, scoliosis can be corrected from the posterior approach by a compression maneuver on the convex side and distraction on the concave side simultaneously after performing SPOs at the same segments. Wedge osteotomies can be applied with some modification for a variety of curvatures and spinal pathologies.

Figs. 115.7A to C: Pedicle subtraction osteotomy. Case: A 72-year-old woman with degenerative scoliosis with fixed sagittal imbalance. (A and B) Two-staged combined anterior and posterior procedure was planned. *First stage:* Combined anterior release with bone graft and posterior Smith-Petersen osteotomies from T12 to L3 was performed by rotational correction using segmental pedicle screw fixation. *Second stage:* Posterior correction and fusion with extended pedicle subtraction osteotomy on L4 was performed using intrasacral fixation. (C) Thoracolumbar scoliosis was corrected from 53° to 25°. Sagittal fixed imbalance was corrected to a well-balanced spinal curvature with lumbar lordosis of 52°.

Vertebral Column Resection

The resection of an apical vertebra for the correction of spinal deformity was the first described by MaLennan.³⁷ He has reported posterior resection and correction of the curvature using a postoperative cast. Several surgeons have reported their own modifications for the treatment of congenital spinal deformity, spinal bone tumor, spondylosis, etc.³⁸⁻⁴¹ However, all procedures for the resection of the VCR were through combined anterior and posterior approaches. Suk first introduced posterior VCR (PVCR) for the treatment of severe spinal deformities in 2002.⁸ Since then, several surgeons have attempted to perform posterior VCR (PVCR) for the correction of rigid angular spinal deformities.⁴²⁻⁴⁸ Several approaches can be modified and selected for posterior resection of the vertebral column. A pure PVCR, PVCR followed by a staged anterior procedure for an anterior column support, or one-staged or two-staged anterior and posterior combined VCR may be chosen based mainly on the experience of the surgeons or the special features of the spinal deformities.

Vertebral column resection is regarded as the most powerful procedure for obtaining the best correction of even the most rigid spinal deformities in all osteotomy procedures. Vertebral column resection may be indicated for angular rigid kyphosis or severe scoliosis >100–120° (with flexibility <25–30%) as other osteotomies methods

are insufficient in correcting such spinal curvatures (Figs. 115.8A and B). The most common indications for VCR are congenital rigid spinal deformities. Among these, hemivertebrectomy has been widely accepted as the standard procedure for surgical treatment even in the very young pediatric patients,⁴⁹⁻⁵¹ although this may not be regarded as a pure VCR because it is a unilateral VCR, not bilateral.

Surgical Technique for VCR

As described already, VCR can be performed through either a combined anterior and posterior approach or a posterior only approach. One of the reasons combined anterior and posterior approach may be chosen is that the surgeon may have limited experience with PVCR. In addition, a curve may benefit from a circumferential release due to the periapical rigidity to obtain better correction. It is usually very difficult to perform anterior release at the apical segments for severe scoliosis; thus, surgeons that choose anterior release and bone graft in the periapical regions may perform a double thoracotomy approach to access at least four or five intervertebral disc spaces. Two discrete thoracotomies are placed with preservation of at least two ribs between them for the stability of the chest cage. The rib heads should be resected, and internal thoracoplasty along the periapical convex of the thoracic cage may be added at the same time. This may be helpful for posterior exposure of the apical convex side.

Figs. 115.8A and B: Vertebral column resection for severe rigid scoliosis. Case: A 25-year-old woman with congenital scoliosis (mixed type) (A). Posterior vertebral column resection on T9 was performed with multiple Smith-Petersen osteotomies on several adjacent cranial and caudal segments. Scoliosis was corrected from 125° to 79° by cantilever and derotation maneuver (B).

The posterior approach may be performed with or without anterior release. Paravertebral muscles are dissected subperiosteally and exposure of the posterior structure should be thoroughly performed bilaterally to the tip of transverse processes. Exposure of the apical several laminae on the convex side is quite difficult in cases of severe angular scoliosis, due to the overlying ribs on the laminae. Screw insertion may be the next step followed by soft tissue release and bony release, including periapical multiple chevron-shaped osteotomies (SPO or Ponte). This decision is dependent on the rigidity/severity of the curvatures, or by the surgeon's preference. Screw insertion must proceed before osteotomies to stabilize curvatures during VCR procedures by placing temporary rods to prevent subluxation or angular translation. The recently developed computer guided system can be helpful for the accurate insertion of pedicle screws even into small apical pedicles on the concave side. Vertebral column resection is usually performed at the apex with multiple other posterior osteotomies (SPO or Ponte osteotomy) on the periapical and secondary curves if it is very rigid. SPO or Ponte osteotomies or partial facetectomies are planned preoperatively on every segment that should proceed before VCR. Vertebral column resection makes the spinal column dramatically unstable and performing other osteotomies may irritate or damage the neural tissues under these conditions.

Actual VCR procedures require laminectomies, bilateral facetectomies, and proximal rib resection (costo-transversectomy) using osteotomes, curettes, or Kerrison rongeurs at the level of the apical vertebrae. Ribs and spinous processes can be resected to use as strut grafts for the intervertebral defect or as bridging bones into the laminectomy gaps after correction. Careful exposure of the dural sac and nerve roots is extremely important. It may be necessary to ligate nerve roots at the proximal site in the thoracic spine to make a wider working space for resection of vertebral bodies in the thoracic spine. The pedicles can be isolated by resecting the surrounding bones and soft tissues. Pediculectomies on the concave side are particularly risky because the spinal cord rests very closely to the concave pedicle. The concave pedicles may become the cause of paralysis due to kinking of the spinal cord during VCR. The pedicles on the concave side may be thin and entirely cortical. Pedicles that are very hard and difficult to remove can be thinned by the use of high-speed bar to allow a much safer resection. Pediculectomies on the convex side are performed followed by subperiosteal exposure of the lateral wall of target vertebral body and resection. Thoracic nerve roots on the convex side may be also ligated to gain access for the remaining procedure. Cranial and caudal intervertebral disc tissues and cartilage are also removed to expose adjacent bony vertebral endplates. The posterior cortex of the vertebral body is the last part of resection. Meticulous bipolar cauterization of

epidural vessels for control of bleeding is essential and the longitudinal ligament is disconnected together with epidural vessels to free the dural sac from the vertebral body. The last structure of vertebral body can be mashed and removed by using curved impactors or special instruments designed for this procedure. It is very important to stabilize the spinal column during all these vertebral body resection procedures, by placing temporary rods (one or two) with at least two pedicle screws above and below in order to prevent subluxation or spontaneous closure of the osteotomy gap that may cause spinal cord irritation. Correction can be achieved by compression applied onto the temporary rod or the rod for fixation on the convex side. Shortening of the vertebral column can be too excessive causing the dural sac to sag onto the spinal cord, therefore an anterior structural cage should be placed to prevent this. Local bone graft (i.e. rib) or an appropriate size of cages should be placed to stabilize and to achieve solid fusion if the surgeon suspects that there will be space remaining in the anterior column. Temporary rods placed earlier are individually changed to permanent rods and compression is applied to stabilize the vertebral column after bone grafting (rib or spinous process) the laminectomy defect. Therefore, covering the dural sac as a bone bridge is helpful, not only to protect the spinal cord but also to facilitate bone fusion.

APPLICATION OF OSTEOTOMY PROCEDURES AND BONE UNION

Single or combined use of vertebral osteotomies dramatically increases the ability to correct severe spinal deformities. Recent reports of the surgical outcomes for severe spinal deformities describe their superiority in correction and clinical outcome.⁴⁵ These procedures change the strategic planning for treating not only severe rigid curvatures but also even for moderate scoliosis. This trend occurred due to the development of segmental pedicle screw fixation that provides strong correction and stabilization of the spinal column. However, the coupling of pedicle screw fixation and a combination of vertebral osteotomies can represent “a double edged sword.” In particular, an extensive osteotomy via a posterior approach can achieve much better correction, but it can destroy the bony continuity between adjacent vertebrae including facet joints and intervertebral discs. The short-term outcome has been reported to be excellent in terms of correction of rigid spinal deformity, due to the stabilizing force of pedicle screw fixation.^{44,-47,52,53} However, failure to achieve bone fusion

due to the unsatisfactory quality and quantity of grafted bone or malposition of grafted bone will lead to poor long-term outcome due to pseudarthrosis, screw loosening and/or back-out, rod breakage, and newly occurring neurological deficits. There have been few reports describing bone union in long-term follow-up studies. This is partly because pedicle screw fixation is strong enough to secure the spinal column, so that pseudarthrosis and screw loosening may be latent, or partly because it is very difficult to evaluate bone union in patients who underwent posterior fusion with spinal instrumentation using plain X-ray images. Smith et al.⁵⁴ reported that the rate of rod fracture in patients who underwent posterior instrumented fusion in adult scoliosis is 6.8%. They described that the rate of rod fracture is much higher (15.8%) after PSO. Surgeons should always pay attention to the location in reconstructed spinal column where bone union would take place if they decide to conduct vertebral osteotomies and bone graft (Figs. 115.9A to C).

KEY POINTS

- Vertebral osteotomies can be mainly categorized into three types: posterior chevron-shaped osteotomy, wedged-osteotomy including posterior subtraction osteotomy, and VCR.
- Preoperative evaluation and construction of a valid strategy for the correction of the spinal deformity are very important and surgeons should decide which type of osteotomies and how many segments must be osteotomized to obtain the maximum correction of either scoliosis and/or kyphosis.
- Obtaining 5–10° per one segment is the approximate goal for chevron-shaped osteotomy. Surgeons must understand its limitation of correction when they choose chevron-shaped osteotomy for the surgical treatment of spinal deformity.
- The key of posterior wedge osteotomies (including PSO, TDO, and VCR) is to control the bleeding from the epidural vessels or basivertebral vessels during removal of vertebral bodies
- Vertebral wedge osteotomies, in particular posterior VCR, are very challenging surgical procedures with a requirement of well-experienced surgeons and surgical teams. Surgeons must not only understand principles and surgical procedures of osteotomies but also obtain meticulous surgical skills when choosing vertebral osteotomies for the surgical treatment of severe spinal deformities.

INTRODUCTION

The bone quality of the spine plays an important role in the planning of surgical intervention for spinal deformities. Patients with osteoporosis may require surgical intervention including spinal instrumentation for several reasons, including severe mechanical pain due to sagittal or coronal imbalance, radicular pain or neurogenic claudication due to central canal or foraminal stenosis in the setting of adult degenerative scoliosis, and spinal instability or neurologic deterioration after a spinal trauma.¹ Although long spinal fusions in elderly patients is somewhat controversial, some studies have shown that elderly patients can obtain as much clinical benefit as their younger counterparts (≤ 55 years of age) after spinal deformity surgery.²

However, it has been shown that pedicle screw instrumentation of the osteoporotic spine carries an increased risk of surgical complications. Despite being the most rigid form of posterior instrumentation, pedicle screws may provide insufficient strength for rigid fixation and fusion in patients with osteoporosis. It has already been demonstrated that there is a positive correlation between bone mineral density (BMD) and the maximum torque required to insert a pedicle screw.³ A 5-year follow-up series of instrumentation in patients with osteoporosis demonstrated that the rates of pedicle fractures and compression

fractures may reach up to 13%, while progressive junctional kyphosis may occur in up to 26% of patients.⁴ These series also found an increased incidence of other late complications after spinal fusion in patients with osteoporosis, including pseudarthrosis with instrumentation failure, adjacent-level disc degeneration and progressive kyphosis.

Despite the strong evidence of the detrimental effects of poor bone quality in the postoperative outcomes of patients submitted to spinal instrumentation, it seems that the majority of the spine surgeons still fall short in performing an adequate preoperative evaluation of a patient's bone quality. For example, a questionnaire applied to spine surgeons attending a conference on disorders of the spine demonstrated that a large percentage of spine surgeons do not routinely screen for osteoporosis or osteomalacia before considering surgical intervention including spinal fusion.⁵

EPIDEMIOLOGY OF OSTEOPOROSIS

It has been estimated that osteoporosis currently affects more than 10 million people in the U.S. As the average age of the population increases, it is expected that a greater percentages of patients with spinal problems will be affected by this condition. Although osteoporosis is generally considered a disease of aging, other factors may significantly

influence the bone quality including mechanical issues (e.g. weight), physical activity, and nutrition (such as the overall intake of vitamin D and calcium), smoking, as well as medications (such as glucocorticoids and some hormonal treatments).^{6,7} Other secondary causes of osteoporosis are celiac disease, impaired renal function, diabetes mellitus, and renal tubular acidosis.⁷³

■ PATHOPHYSIOLOGY OF OSTEOPOROSIS

The most important factors related to bone quality are age and genetic factors, with many gene polymorphisms which affect bone mineral density having already been identified.^{8,9} Osteoporosis is characterized by loss of bone mass with deterioration of the general bone microarchitecture which occurs as a result of a dysfunction involving endocrine factors and their target cells in the bone. The two cells directly involved in bone homeostasis are the osteoclast, responsible for bone resorption, and the osteoblast, responsible two populations of cells for bone formation. Normally, these two populations of cells produce a stable equilibrium of bone formation and remodeling.^{8,10} If the activity of any of these cell populations become dysregulated, the final outcome may be osteoporosis.^{11,12}

In women, the bone mass reaches its peak around 25 years, while presenting an accelerated decline during the perimenopausal and postmenopausal period. It is also known that the rate of bone loss decreases yearly after the menopause, so that the slope of the curve depicting the decline in the bone mineral density (BMD) becomes less accentuated with progressing age. Conversely, it has already been shown that men present a slow and constant decline in BMD with aging without a faster decline in specific time points, such as the one which occurs in women in the perimenopausal period. It has been estimated that around the age of 60–65 both women and men will have equal rates of bone loss with the progressive decline leading to the lowest point for BMD values at the age of 80 years.^{7,13}

Aging, the greatest risk factor for osteoporosis, has been shown to lead to several changes in bone histology, including osteocyte death, increased bone turnover, thinned trabeculae, decreased cortical width, and increased cortical porosity.^{11,12,13} Another important etiological factor which must be taken into when evaluating a patient with osteoporosis is acute weight loss (either pathological—due to cancer, for example—or iatrogenic—after bariatric surgery).

The pathophysiology of such association between weight loss and bone mineral density has been shown to be multifactorial and to strongly correlate with the speed of weight lost. Decreased calcium, vitamin D, and protein intake during periods of caloric restriction have been shown to lead to decreased calcium absorption, increase in PTH, and increased bone resorption.⁷⁴

The main pathophysiological mechanism of osteoporosis in patients with diabetes mellitus is decreased bone formation, as insulin and IGF-1 have been demonstrated to have an anabolic effect on bone. Additionally, in vitro studies have also shown that sustained exposure to high glucose concentrations leads to osteoblast dysfunction, so that poor metabolic control may have a clear negative impact on bone mass.⁷⁵

The pathophysiology of steroid-induced osteoporosis include direct inhibition of osteoblast function, direct enhancement of bone resorption, inhibition of gastrointestinal absorption of calcium, increased urine loss of calcium and inhibition of sexual steroids.⁷⁶

■ DIAGNOSIS OF OSTEOPOROSIS

Osteoporosis can be defined as the presence of low bone mineral density with associated microarchitectural deterioration of the bone tissue, ultimately leading to bone fragility and increased risk of fractures. According to the World Health Organization (WHO) the diagnosis of osteoporosis should be based on BMD measurements obtained on dual energy X-ray absorptiometry (DEXA).¹⁴

Osteoporosis is defined as a BMD of 2.5 or more standard deviations below the peak bone mass for young healthy adults (T-score \leq 2.5). Regarding the investigation of osteoporosis, besides the DEXA scan, only a few laboratory tests are recommended including serum calcium, complete blood count, 25-Hydroxyvitamin D, T3, T4 and thyroid stimulating hormone (TSH). Serum electrophoresis should be considered for those patients with vertebral fractures in which the diagnosis of multiple myeloma is suspected.⁹

A DEXA scan should be obtained in any patient over 65 years of age or in younger patients with any of the following: Fragility fracture (a fracture involving mechanical forces that would not ordinarily cause a fracture in a healthy young adult), prolonged use of glucocorticoids, hypogonadism or premature (\leq 45 years) menopause, presence of any gastrointestinal malabsorption syndrome, primary hyperparathyroidism, parental history of hip

fracture, long-term smoking, high alcohol intake, low body weight or recent major weight loss, rheumatoid arthritis, incidental finding of a bone fracture or osteopenia in a recent X-ray, or the presence of any other comorbidity that may be associated with increased bone loss.^{9,13,15}

MEDICAL TREATMENT OF OSTEOPOROSIS

Calcium and Vitamin D

The main role of calcium and vitamin D supplementation in the management of osteoporosis is to prevent a further decrease in the BMD rather than any active role in new bone formation. Although there are some controversies about the effectiveness of calcium and vitamin D, a large recent meta-analysis published in “The Lancet” concluded that the benefit suggested by several studies in the literature, together with the associated low costs of such supplementation supports its general use for prevention of osteoporosis in patients beyond the age of 50 years. Regarding their influence upon the BMD, it has been shown that the best therapeutic effect can be achieved with daily doses of 1200 mg of calcium and 800 IU of vitamin D.¹⁶

Biphosphonates

The medical treatment with greatest impact for patients with osteoporosis consists in the use of biphosphonates. Biphosphonates are drugs which inhibit osteoclast activity by binding to the hydroxyapatite present in the bone. There are several drugs in this class, with the two most popular ones being Alendronate and Risedronate.¹⁷ Biphosphonates are well-known for their gastrointestinal side effects that may decrease compliance, such as vomiting, diarrhea, gastritis, nausea, inflammation and ulcers.^{18,19}

Despite the fact that early experimental models have suggested that biphosphonates might inhibit spinal fusion,^{77,79} recent studies in animals with osteoporosis have demonstrated that alendronate, in fact, increased the radiologic and histologic surrogate markers of spinal fusion, with increased final biomechanical strength and new bone formation.⁷⁸

In relation to clinical studies, a recent prospective randomized trial which employed a protocol of initiating alendronate right after the surgical procedure (35 mg/week) versus a control group in which only vitamin D (alfacalcidol—1 µg/day) was used, found that bridging bone formation was more frequently observed in the alen-

dronate group at all postoperative assessment periods. Additionally at 1-year postoperative follow-up, a solid fusion was achieved in 95% of the patients in the alendronate group versus 65% of those in the control group. Cage subsidence (> 2 mm) was observed in 5% of the patients in the alendronate group and 29% in the control group, and while no vertebral fractures were observed in the alendronate group, 24% of patients in the control group presented subsequent fractures.⁸⁰

Therefore, according to the authors of this study as well as a recent expert editorial, a protocol of alendronate initiated immediately after surgery and maintained for 3 months postoperatively seems to provide significant benefits for patients with osteoporosis undergoing spinal fusion.^{80,81} Similarly, in those patients already under use of such drug, there is no clinical evidence supporting its discontinuation either before or after spinal fusion.

Partial Estrogen Agonists and Antagonists

Although they were primarily developed to decrease postmenopausal symptoms, estrogen agonists have been shown to significantly increase BMD and, therefore, have also found application as an adjuvant treatment in patients with severe osteoporosis and suboptimal management with first-line drugs (such as bisphosphonates). Although estrogen agonists strongly decrease the incidence of hip and spine fractures they are not routinely used as first choice for the treatment of osteoporosis, as its use in women over the age of 60 years have been demonstrated to increase the risks of venous thromboembolism, coronary artery disease, and breast cancer. These medications also do not possess a long-term durable effect in terms of bone quality (e.g. if stopped before 60 years of age, they are not able to prevent fractures later in life).²⁰⁻²²

Selective estrogen receptors modulators (SERMs) such as Raloxifene and Bazedoxifene have also been shown to decrease the risk of vertebral fractures by 30–50% in women belonging to the high-risk group according to the Fracture Assessment Risk of the WHO. Additionally, the risks of thromboembolism with these medications are lower in comparison with the standard estrogen replacement therapy.^{22,23}

Parathyroid Hormone

Parathyroid hormone (PTH) has the ability to improve bone quality by specifically targeting the bone microarchitecture.

In fact, by improving the density of the trabecular connectivity and collagen cross-link formation, therapy with PTH analogues has been shown to lead to increased bone strength and mechanical resistance.²⁴

This effect on the microarchitecture of bone does not occur with biphosphonates and, therefore, some authors believe that there may be an opportunity for combining both classes of medications. The main drug in this class is teriparatide, a recombinant human PTH. Although not routinely used in the clinical practice, the greatest benefits of PTH analogues are seen in patients with multiple risk factors for osteoporosis, such as: low body mass index, use of glucocorticoids and gastrointestinal disorders that inhibit the absorption of vitamins and electrolytes.^{22,24}

In relation to its use in spinal surgery, a recent prospective randomized trial demonstrated that daily subcutaneous injection of 20 µg of teriparatide (Forteo®), form of administered for 2 months before and 8 months after surgery, was more effective in promoting fusion than biphosphonates (bone union rate of 82% in the teriparatide group versus 68% in the bisphosphonate group) after instrumented lumbar posterolateral fusion with local bone grafting in women with post-menopausal osteoporosis.⁸²

Therefore, according to a recent systematic review, there is already evidence that recombinant PTH improves the fusion rate and fusion mass microstructure, and therefore it constitutes an interesting option for treating osteoporosis in patients requiring complex spine surgery.

■ COMPLICATIONS OF DEFORMITY SURGERY IN OSTEOPOROTIC PATIENTS

As already mentioned several studies have demonstrated that osteoporosis is an important risk factor for complication after deformity surgery.^{4,25} Although most of these complications are related to pseudarthrosis and hardware loosening, it is important to remember that other complications, such as graft subsidence, adjacent segment fracture and even infection (as the results of a recent study seems to suggest)²⁶ occur more often in complex spine surgery in osteoporotic patients.

Similarly, in the setting of adult degenerative scoliosis (the scenario in which most of the deformity surgeons will face osteoporosis), it has already been demonstrated that patients with osteoporosis present higher complications rates than those without it. Early complications include pedicle fractures and compression fractures. Late complications include pseudarthrosis with instrumentation

failure, adjacent-level disc degeneration, compression fractures, and progressive kyphosis.¹

Pseudarthrosis

Multiple studies have already demonstrated that pedicle screw fixation alone is less effective in osteoporotic bone.^{4,27-29} Previous investigations regarding the failure mechanisms after pedicle screw fixation have demonstrated that translational motion, causing a “windshield wiper” effect and leading to loosening of the screws is one of the most important causes of pseudarthrosis after spinal instrumentation in osteoporotic patients (Figs. 116.1A to E).^{30,31}

Regarding adult complex deformity surgery, it is important to remember that it has already been shown that incomplete sacropelvic fixation significantly increases the risks of pseudarthrosis and that the clinical outcomes scores are adversely affected when pseudarthrosis develop (Figs. 116.2A to E).³² Therefore, it is highly advisable that major thoracolumbar fusions for treatment of deformity in patients with osteoporosis include a strong sacropelvic fixation.

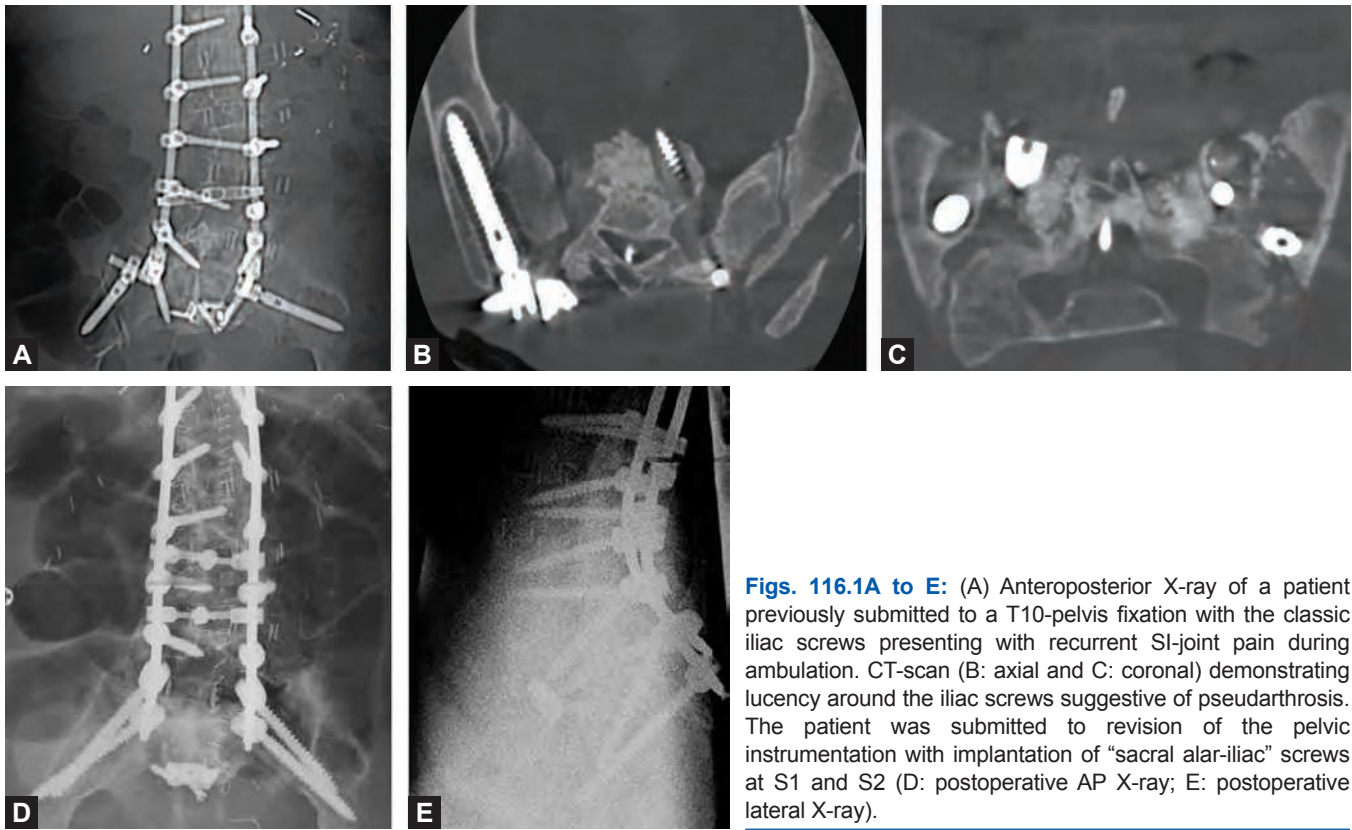

Most series dealing with complex deformity surgery in the elderly report a very high risk of overall complications at the long-term follow-up (more than 30% at 5 years).³³ Most of these complications are related to mechanical failure and pseudarthrosis, which usually require a second procedure in order to deal with broken rods, loose screws or to extend the fusion to adjacent affected levels.^{34,35}

Graft Subsidence

Implant subsidence is a frequent complication of interbody fusion in osteoporotic patients after both lumbar and cervical fusion.³⁷ As the interface between a spinal implant and vertebral body, the endplates play an important role in sharing the axial load forces between adjacent vertebral bodies. A cadaveric study demonstrated that BMD inversely correlates with the rates of lumbar endplate failure after axial load.³⁶

Adjacent Segment Fracture

In a study comparing BMD using Hounsfield units (HU), a quantitative scale for describing radiodensity, from computerized tomography scans in patients with adjacent segment fractures following spinal fusion, the authors demonstrated that HU values at the fracture level were

Figs. 116.1A to E: (A) Anteroposterior X-ray of a patient previously submitted to a T10-pelvis fixation with the classic iliac screws presenting with recurrent SI-joint pain during ambulation. CT-scan (B: axial and C: coronal) demonstrating lucency around the iliac screws suggestive of pseudarthrosis. The patient was submitted to revision of the pelvic instrumentation with implantation of "sacral alar-iliac" screws at S1 and S2 (D: postoperative AP X-ray; E: postoperative lateral X-ray).

significantly lower in the fracture group compared to controls. Similarly, the global assessment across the whole thoracic and lumbar spine using HU units demonstrated significantly lower values in the fracture group, suggesting that osteoporosis may be an important risk factor for adjacent-segment fracture following a spinal fusion.³⁸

Infection

In addition to commonly known risk factors for surgical site infections such as age, obesity, diabetes, tobacco use, and estimated blood loss, a recent study demonstrated that osteoporosis may also be an independent risk factor for postoperative infection after spine surgery.²⁶

SALVAGE TECHNIQUES FOR DEFORMITY SURGERY IN OSTEOPOROTIC PATIENTS

Cement Augmentation

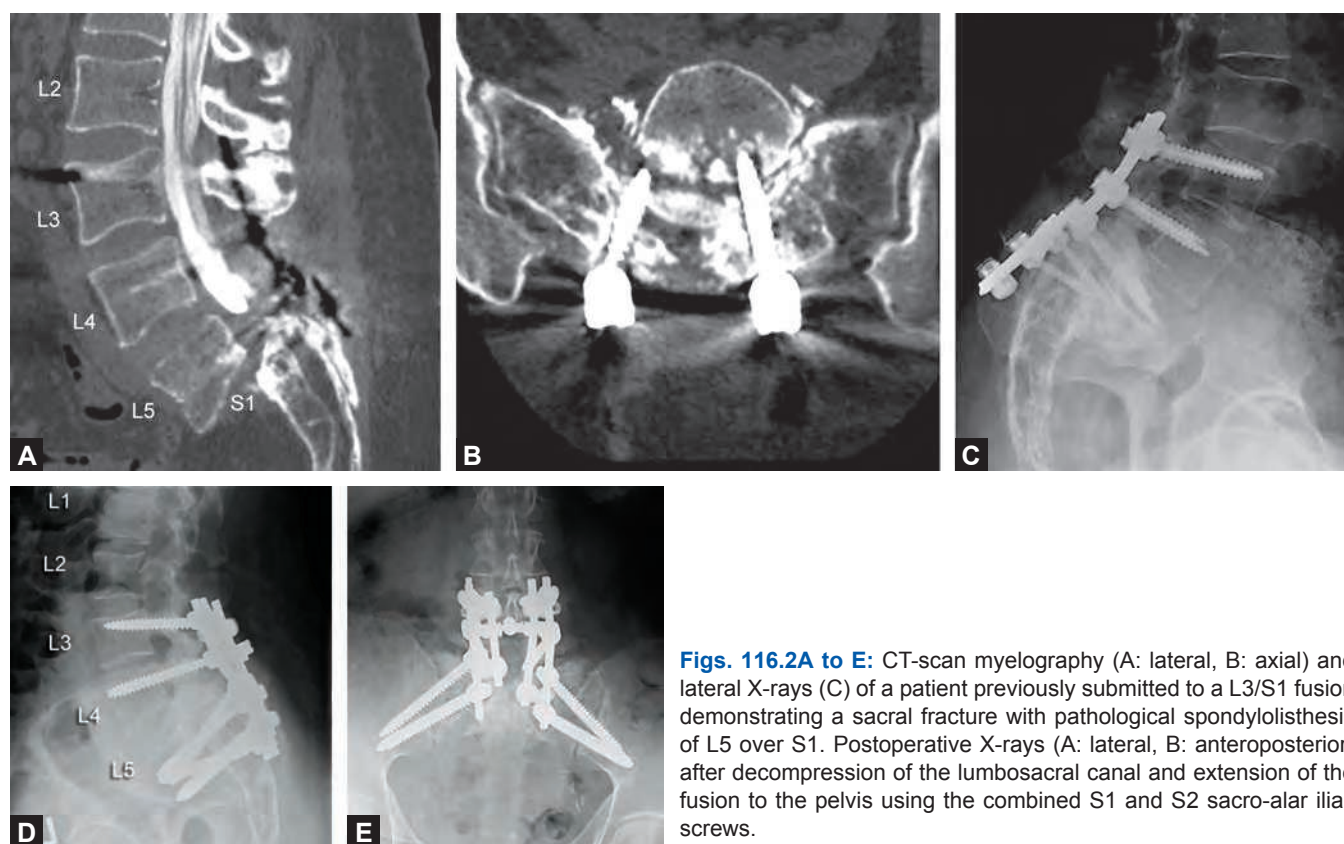

A recent cadaveric study has demonstrated that cement (polymethyl methacrylate [PMMA]) augmentation of pedicle

screws instrumentation in osteoporotic vertebrae using the conventional kyphoplasty technique significantly increased the pullout strength of screws in comparison to a control vertebrae with no cement augmentation.³⁹

A recent survey among Germans spine surgeons (composed of both orthopedic and neurosurgeons) demonstrated that nearly 80% of the participants routinely use cement-augmented pedicle screws in their daily practice. Moreover almost 2/3 of the specialists affirmed that they also use cannulated screws or other specially designed screws in the setting of osteoporosis.⁴⁰

Another study which investigated the relationship of polymethyl methacrylate augmentation and the incidence of postoperative pseudarthrosis after instrumentation of osteoporotic vertebral fractures found that the incidence of clear zones around the pedicle screws were significantly lower in the cement-augmented group in comparison with the control group (29.4% vs 71.4%). Moreover long-term loss of intraoperative curve correction was significantly lower (3 degrees vs 7.2 degrees) and the fusion rates were significantly higher in cement-augmented group (94.1% vs 76.1%).⁴¹

A study which compared the pullout strength of fenestrated titanium screws specifically designed for cement

Figs. 116.2A to E: CT-scan myelography (A: lateral, B: axial) and lateral X-rays (C) of a patient previously submitted to a L3/S1 fusion demonstrating a sacral fracture with pathological spondylolisthesis of L5 over S1. Postoperative X-rays (A: lateral, B: anteroposterior) after decompression of the lumbosacral canal and extension of the fusion to the pelvis using the combined S1 and S2 sacro-alar iliac screws.

augmentation with standard titanium screws demonstrated that the fenestrated screws demonstrated significantly greater insertion torques, leading to more effective and lasting purchase in patients with poor bone quality.⁴²

Bone Morphogenetic Protein

The use of bone morphogenetic protein (rhBMP-2) has been evaluated as an adjunct for fusion in the elderly.⁴³ A prospective randomized controlled trial comparing bone grafting with rhBMP-2 versus iliac crest bone graft for lumbar spine fusion in patients over 60 years of age demonstrated greater improvement in Oswestry Disability Index (ODI) and Short Form-36 physical component score (SF-36) in the rhBMP-2-infused graft group in comparison with the iliac crest bone graft group. The study also demonstrated lower rates of complications and revision procedures in the rhBMP-2 group. Additionally the fusion rates as evaluated by CT-scan were significantly higher in the rhBMP-2-infused graft group in comparison with the iliac crest bone graft group.⁴³ In a follow-up cost-analysis, although the mean cost of the initial admission

was slightly higher (\$36,530) in the rhBMP-2 group than in the iliac crest bone graft group (\$34,235), the total cost of care over 2 years was higher in the iliac crest bone graft group (\$42,574) in comparison with the rhBMP-2 group (\$40,131).

Special Pedicle Screws

Although still not widely available in the clinical practice, a newly designed “expandable” pedicle screw has been demonstrated to be able to support an axial load 25% greater than the maximum load supported by standard pedicle screws. Additionally, the energy required to cause bone-implant failure was also statistically greater for the expandable screw when compared with a traditional pedicle screw.⁴⁴

Intraoperative Image-guidance

Besides the advantage of improving the rates of successful pedicle screw placement in situations of distorted anatomical landmarks, intraoperative navigation enables placement of longer screws with bi-cortical purchase

(both in anterior and posterior approaches), as well as the option of different trajectories of screw placement. A more lateral pedicle screw trajectory which engages the lateral cortex of the vertebral body has been shown to increase the axial pullout strength by approximately 30%, therefore significantly minimizing pedicle screw loosening in patients with poor trabecular bone.⁴⁵

Extension to the Pelvis

The ideal technique for spinal instrumentation in a patient with poor bone quality involves the use of multiple points of fixation above and below the apex of the deformity.¹ The use of pelvic fixation is an important tool in deformity surgery (especially in osteoporotic patient), as it provides a strong anchor for long thoracolumbar constructs.²

Pelvic fixation is routinely used in spinal deformity surgery for two main purposes: to enable better correction of the deformity (especially if the apex or the curve is in the lumbar spine) and to increase the stability of fixation at the lumbosacral junction in order to avoid a pseudarthrosis. Pelvic fixation also enables correction of the pelvic obliquity in the context of long thoracolumbar constructs.

The two classic procedures used for pelvic fixation are the “Galveston technique” and the “Iliac wing screw.”⁴⁶ The Galveston technique was developed by Allen and Ferguson in the early 1980s and consists of a rod inserted longitudinally between the two cortical plates of the ilium.⁴⁷ Although this technique received significant enthusiasm by the spine community at the time of its proposal, undergoing several technical modifications throughout the years,⁴⁵ it has the inherent disadvantage of requiring complex three-dimensional bending of the rods.

At the present time the most widely performed technique for pelvic fixation is the use of pelvic screws inserted into the iliac wing with an entry-point at the posterior superior iliac spine (PSIS).^{45,48,49} Biomechanical studies have demonstrated that iliac screws provide a pullout resistance at least three times greater than the standard Galveston technique.⁵⁰

Although widely used in deformity surgery, sacral fractures and tumors, iliac screws still have some important drawbacks. Due to their lateral entry-point in the ilium and their craniocaudal proximity to S1 screws it is almost impossible to bend the rod to fit into the tulip head of both screws, so that, in most cases, a side-to-side connector that crosses the paraspinal muscles is often required. Moreover, because the entry-point of the classic iliac screw at the PSIS is very superficial, some patients (especially

those with low BMI) may present with an unaesthetic and uncomfortable prominence of the screw head under the skin at its entry point.⁵¹ Also, because the harvesting site of the iliac crest graft (whenever used) is usually in close proximity to the entry-point of iliac screws at the PSIS, there may be the potential for significant compromise of the bony integrity of the ileum with the potential for fracture of the superior portions of the ileum.

Several studies have demonstrated that SI-joint pain may be an important cause of the so-called “failed back syndrome,” with an estimated incidence between 29% and 40% of cases in which postoperative chronic low-back pain is observed.^{32,57,58} A finite element study, for example, demonstrated that there is increased motion and stress within the SI joint in patients submitted to L4-L5, L5-S1, and L4-S1 instrumentations in comparison to non-operated patients.³² Additionally, other studies have demonstrated an increased local uptake in the SI joint on both conventional bone scintigraphy (bone-scan) and single-photon emission computed tomography (SPECT) after lumbar fusion, suggesting that biomechanical changes after lumbosacral fusion may contribute to SI joint stress, inflammation, degeneration and pain.⁵⁴ Therefore, “disrupting” and fusing the SI joint may be a method of avoiding such a painful occurrence.

The technique for placement of “sacral alar-iliac” screws was first described in 2007 in a series of 32 pediatric patients,⁵² and was later employed by clinical studies of deformity surgery in the adult population.⁵³⁻⁵⁵ This technique allows for a screw entry point between the S1 and S2 posterior foramina with the screw traversing the SI joint and then into the ileum. The advantage of this modified screw entry point allows for a low-profile screw (related to their deeper entry-point) and easier alignment with the upper pedicle screws. Due to the fact that the superior portion of the lateral sacral projection to the ilium corresponds to a nonarticular area (Figs. 116.3A and B) it has been reported that “sacral alar-iliac” fixation may not necessarily violate the true SI joint, although in according to a previous report such violation occurs in approximately 60% of the cases.⁵⁶

Surgical Anatomy of Sacral Alar-Iliac Screws

In order to properly describe the anatomical landmarks for placement of “sacral alar-iliac” screws, a basic review of the anatomy of the posterior sacral region is necessary. The human sacrum is a large triangular bone com-

Figs. 116.3A and B: (A) Medial view of the Ilium. The projection of the lateral sacral mass on the outer table of the posterior ilium has a triangular shape. The superior portion of the projection consists mainly of a nonarticular surface, while the inferior one (with an anterior upward limb) consists to an articular surface. (B) Lateral view of the sacrum. Note the similar form of the articular portion of the sacrum (called “auricular surface”—in blue) and the articular portion of the ilium.

posed by five separate vertebrae that are fused along with their intervening intervertebral discs. The dorsal surface of the sacrum is convex in shape and marked by several longitudinal crests coursing in a rostrocaudal direction (Fig. 116.5). The prominent “median sacral crest” is derived from the rudimentary spinous processes of the upper three or four sacral vertebrae that fused together. Usually it is possible to observe 3 or 4 median tubercles (the remnant of the rudimentary spinous process), with the S1 tubercle being more prominent and distinct from the rest.⁶⁴

Lateral to the “median sacral crest”, on each side, there is a depression called the “sacral groove”, which is formed by the fusion of the rudimentary sacral laminae. Lateral to sacral grooves there is a series of indistinct intermediate tubercles (representing the fused articular processes of the sacral vertebrae) which form another longitudinal crest, called the “intermediate crest”. The intermediate tubercles of the fifth sacral vertebra form the so-called “sacral cornua”, which articulates with the corresponding coccygeal cornua.

The four posterior sacral foramina are located laterally to the “intermediate sacral crest”. They are usually smaller in size and less regular in form than the anterior sacral foramina and transmit the posterior divisions of the sacral nerves.⁶⁵ The lamina of the fifth sacral vertebra (and sometimes those of the fourth) commonly fail to fuse at

the midline, giving rise to the “sacral hiatus”, a bony gap in the posterior wall of the sacral canal which can be used for anesthetic purposes, such as the “caudal epidural block.”⁶⁶

Laterally to the posterior sacral foramina there is another crest called the “lateral sacral crest”, which forms the boundary between the “body of the sacrum” and the “lateral sacral mass” (also called “pars lateralis”). The “pars lateralis” is formed by the embryological union of the transverse processes of the primitive sacral vertebrae. Because the superior parts of these lateral portions resemble wings (in Latin: *ala*) they are conventionally called “sacral alae”. The sacral alae present a large triangular surface which supports the psoas major muscle and the lumbosacral trunk.⁶⁴

Within the posterior sacral foramina there is a fibrous membrane thought to be analogous to the *ligamentum flavum* of the mobile vertebral column.⁶⁷ A foraminal arterial branch (arising from the lateral sacral artery) is almost invariably present within the foramina. During lateral subperiosteal dissection of the posterior surface of the sacrum in order to identify the entry-point of the “sacral alar-iliac” screw, it is frequent to observe bleeding from this artery, which can be easily controlled with monopolar or bipolar coagulation.

Biomechanics of Pelvic Fixation

From the biomechanical standpoint the lumbosacral base may be divided into three different zones (Fig. 116.4A).⁵⁹

Zone 1 consists of the S1 vertebral body and the cephalad margins of the sacral *alae*. The most common techniques for fixation in zone 1 involves placement of S1 pedicle screws, with the ideal trajectory converging toward the midline, and preferentially, with bicortical purchase of the sacral promontory. Although S2 and S3 pedicle screws are feasible, they do not add much biomechanical strength to the construct due to their short length, and therefore are rarely used. As zone 1 does not provide numerous options for biomechanically-robust fixation, it can be augmented by providing structural anterior inter-body support between L5-S1 and L4-L5-S1 (Fig. 116.4B). It has already been demonstrated, for example, that adding an anterior strut at the L5-S1 or L4-L5 levels changes the instantaneous axis of rotation (IAR) cephalad and, therefore, decreases S1 screw flexion-extension moment by 33%.⁶⁰

Zone 2 includes the sacral *alae* (including the portion of S1 at this level) through the distal sacrum. Although providing some additional biomechanical strength to the construct, zone 2 fixations does not enable major distal

Figs. 116.4A and B: Biomechanical division of the lumbosacral-pelvic junction. (A) Zone 1 comprises the S1 vertebral body and the cephalad margins of the sacral alae above the S1 foramen. Zone 2 includes the rest of the sacral alae and the distal sacrum. Zone 3 consists of the ilium. (B) The biomechanical strength of zone 1 constructs can be “augmented” by adding an anterior column support to the lower lumbar levels (L5/S1 and L4/L5).

Fig. 116.5: Depiction of the posterior anatomy of the sacrum as well as important landmarks for placement of “sacral alar-iliac” screws. Two different entry-points are possible for “sacral alar-iliac” fixation. The first option is the use of an entry-point above the S1 foramen at the level of the “lateral sacral crest” (S1 sacral alar-iliac screws). The second option is using an entry-point localized between the S1 and S2 foramina, also at the level of the “lateral sacral crest” (S2 sacral alar-iliac screw). In cases in which a stronger biomechanical anchor is necessary it is possible to insert both S1 and S2 sacral alar-iliac screws.

anchorage points because of the constraints of the sacral anatomy as well as the high porosity of the medullary bone of the sacrum. Previous studies have shown that

the mid-anterior cortex of the sacral *alae* is the portion of the sacrum with the higher bone density, providing the best screw purchase for zone 2 fixation.⁶¹ Fixation options for zone 2 include: alar screws, sacral hooks and, less commonly, sublaminar wires.⁶² Because of its diverging nature and its multiple fixation points anterior to the IAR, S1 alar screws provides a fixation with intermediate strength between S1 screws alone and S1 screws supplemented by iliac screws.⁵⁹

Zone 3 includes the ilium bilaterally. This region provides the strongest anchorage point for long thoracolumbar fixation constructs. As already mentioned, the Galveston technique, although providing a strong distal fixation option, is technically challenging as it requires a sharp bending of the rod so that it penetrates the ilium in an oblique fashion in the region just above the sciatic notch.⁶³ This form of fixation also provides little resistance to axial pull-out, an important disruptive force during spinal flexion. Finally, studies have demonstrated that micromotion of the SI joint may lead to erosion of the ilium by the rods with symptomatic early loosening.⁵⁹ Therefore, as already mentioned, the Galvestone fixation technique has fallen in disuse, being rarely seeing in current surgical practice.

Operative Technique of Sacral-Alar Screws

In most cases in which pelvic fixation is selected, the fusion length often spans most of the lumbar spine, often extending

Figs. 116.6A to C: (A) Graphic representation of the entry-points and ideal trajectory of the S1 and S2 sacral alar-iliac screws. (B and C) Anteroposterior and lateral (respectively) plain X-rays after a revision surgery for pseudarthrosis of a previous pelvic fixation with iliac wing screws in which a stronger distal anchorage at the pelvis was necessary. Note the placement of both S1 and S2 sacral alar-iliac screws converging toward the upper limit of the sciatic notch.

also into the thoracic spine. It is important to remember that, in order to enable proper identification of the anatomical landmarks for the insertion of “sacral alar-iliac” screws, it is necessary to extend the surgical incision caudally at least 2–4 cm in comparison to that required for placement of S1 screws. In fact, the dissection may need to be extended as distal as the third or fourth sacral segment. In selected cases, it has already been shown that ‘sacral alar-iliac screws’ may also be inserted through a minimally invasive technique.⁵⁴

As the sacral *alae* (or sacral wings) are very wide, there are several potential entry-points in the S1 and S2 portions of the sacral *alae*. Our preferred starting point for the “sacral alar-iliac” screw is located midway between the S1 and S2 foramen and at the level of the “lateral sacral crest” (see Fig. 116.5). Such a starting point usually lines very well with the entry point of the S1 pedicle screw and those of the lower lumbar spine so that no rod bending (or usually a very small medial bending of the rod) is necessary. Such a starting point is located about 25 mm inferior to the superior aspect of S1 and 22 mm lateral to the midline of S2 in the coronal plane.

The ideal trajectory of the “sacral alar-iliac” screw involves approximately 40° of angulation in the anterior direction and 40° of angulation in the caudal direction. Although it is useful to have such angles in mind, the final craniocaudal angle will be ultimately determined by the anteroposterior (AP) and inlet view on fluoroscopic or intraoperative navigation images.

Before reaching the SI joint the “sacral alar-iliac” screw usually crosses a mean distance of 35 mm inside of the sacral bone. After crossing the SI joint, in most of the cases, it is possible to progress the screw inside the ilium additional 35 to 65 mm, so that the final length of a standard “sacral alar-iliac” screw ranges from 70 to 100 mm.

Although most previous reports have described the “sacral alar-iliac” screw as beginning at the alar portion of S2, we have been able to place both a S2-iliac and S1-iliac screw (Figs. 116.6A to C).

Although the classic technique for placement of iliac screws often involves the use of lateral fluoroscopic guidance,⁴⁸ in our experience, the AP and inlet views allow optimum visualization for safe placement of ‘sacral alar-iliac’ screws, as it enables both visualization of the screws crossing the SI joint as well as avoidance of inferior violation toward the sciatic notch.

After defining the initial entry-point according to the aforementioned landmarks, a small initial hole is made with a burr in order to accommodate a power-drill or hand-held probe. At this point, AP-fluoroscopic guidance is used to determine the exact craniocaudal angle of the “sacral alar-iliac” screw. The ideal trajectory is immediately above the notch so that the screw threads are in contact with the cortical bone forming the upper limit of the notch, providing optimal pullout-out strength (Figs. 116.7A to F).

Due to the specific trajectory of the “sacral alar-iliac” screw, anterior violations toward the pelvis are much more

Figs. 116.7A to F: CT-scan (A: coronal, B: sagittal, D: axial) and plain X-rays (C: anteroposterior) of a patient previously submitted to T4/L4 fusion for adult degenerative scoliosis demonstrating fracture of the left sacral alae (left white arrow in A and B) despite the good fusion mass observed between L3 and L5. Note also the presence of air inside the left S1 joint, a sign of advanced spondylotic changes (right arrow in A). Postoperative X-rays (E: AP, F: lateral) after extension of the fusion to the pelvis using the combined S1 and S2 sacro-alar iliac screws.

rare when compared with the classic iliac screws. The width of this screw (usually 8 to 10 mm) combined with such a long bony trajectory (usually 70 to 100 mm, including the two cortical surfaces of the SI-joint) the “sacro alar-iliac” has a very strong purchase.

Because the entry-point for the classic iliac screw at the PSIS is much more lateral in comparison to the entry-points of lumbosacral pedicle screws, it is usually very difficult to bend a rod in order to directly connect the iliac screws with the rest of the lumbosacral screws. This mismatch often

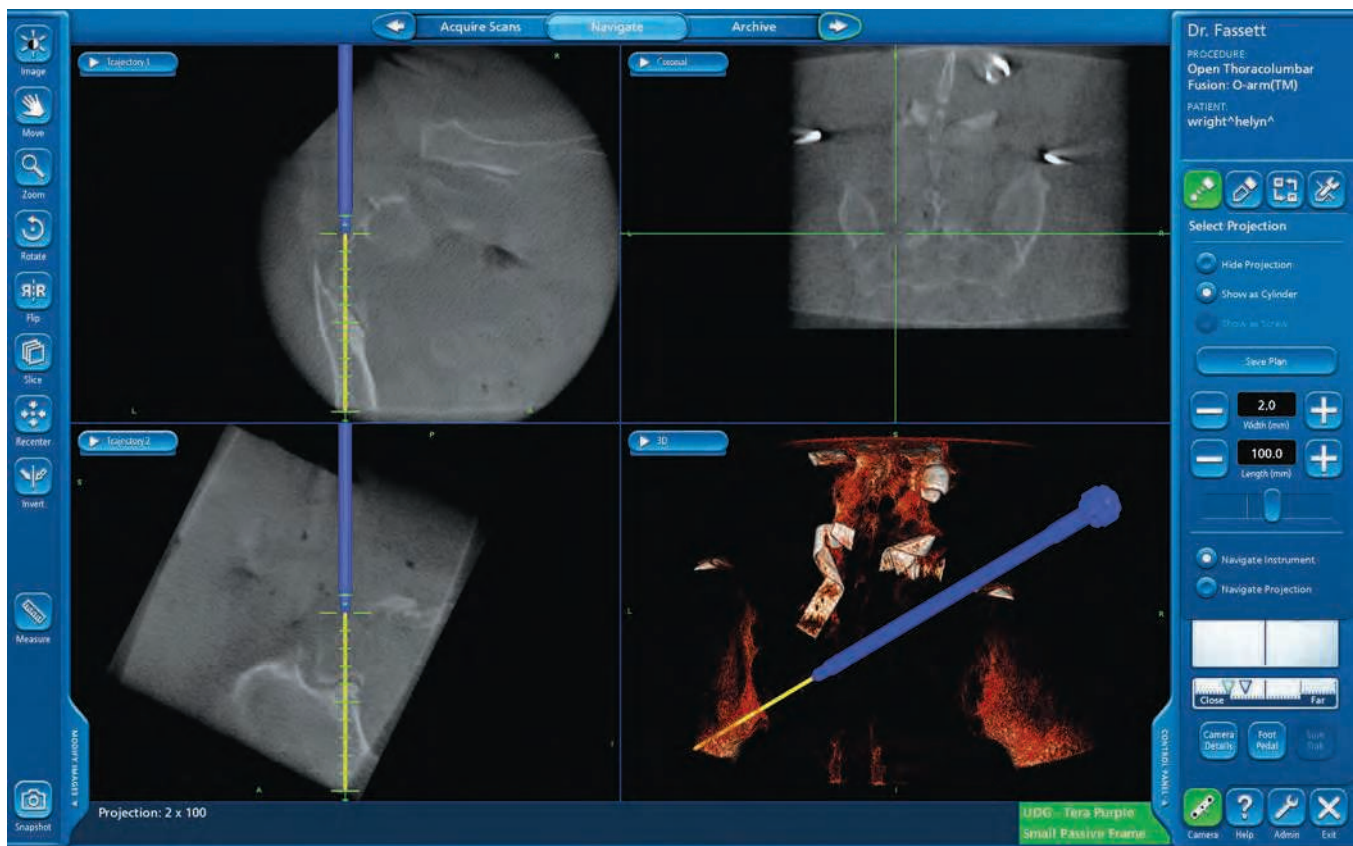

Fig. 116.8: Images of intraoperative CT (O-arm®)-based navigation for placement of sacral alar-iliac screws. Note the ideal projection of the screw crossing the SI joint right above the sciatic notch in the “in-line” trajectories (superior and inferior left) and coronal plane (superior right) as well as anteroposterior radiographic projection).

leads to the necessity of a separate incision in the lumbar fascia as well as the use of off-site connectors. Because the entry-point of the “sacral alar-iliac” screw lies more medially (at the sacral *alae* and not at the iliac bone) is it much easier to connect it with lumbosacral screws, so that usually no (or very little medial bending) of the rod is necessary. Furthermore, in comparison with classic iliac screws, the “sacral alar-iliac” screw requires much less “lordotic” bending of the caudal end of the rod.

Complications of Sacral Alar-Iliac Screws

Although the most common breach observed during placement of “sacral alar-iliac” screws is violation of the posterolateral cortex of the ilium (which usually does not result in any major complications), anterior violations may have several deleterious consequences due to the potential injury to several important vascular, neurologic and visceral structures located inside the pelvis.⁶⁸ Previous

anatomical studies examining the accuracy of “sacral alar-iliac” screws placement have shown that while the rates of posterolateral violations may reach up to 15%, anterior violations are much more rare.⁶⁹ Another dangerous complication of “sacral alar-iliac” screw placement is inferior violation of the sciatic notch. This may lead to injury of the superior gluteal artery and nerve which passes above the piriformis muscle. Injuries to structures that pass below the piriformis, such as the sciatic nerve, pudendal nerve and internal pudendal vessels are much more rare, as they would require a gross inferior violation of the sciatic due an extremely low screw trajectory. Such complications can be easily avoided with the use of plain intraoperative fluoroscopy. In our experience, intraoperative navigation guidance may even obviate the need for intraoperative real time fluoroscopy (Fig. 116.8).

Other possible complications of “sacral alar-iliac” screws are those common to other techniques of pelvic fixation, such as infection (3.7%)⁵⁴ and pseudarthrosis with

screw loosening and chronic SI joint pain. It is important to highlight that radiological studies have reported rates of radiological lucency around “sacral alar-iliac” screws of approximately 4% at a 2-year follow-up,⁵¹ however with uncertain clinical significance.⁵³

CONCLUSION

Patients with complex deformity and osteoporosis constitute a very challenging subgroup of patients in which the rates of complications (such as pseudarthrosis, graft subsidence, adjacent segment fracture and even infection) are significantly higher.^{33,34,70,25,26,72}

Nevertheless, as already previously discussed, the fact that such subgroup of patients present a higher risk of surgical complications after complex spinal procedures does not necessarily mean that the natural history of the conservative treatment provides better long-term results than surgery, nor that older patients should be denied the possible benefits of surgical intervention.⁷¹

In fact, in patients with adult degenerative scoliosis presenting with refractory pain after failed medical treatment and injections, several studies have demonstrated that a major surgical intervention (addressing not only the levels in which there is compression of the spinal canal or nerve roots but also the global spinal deformity) provides a safe “last resort” therapeutic alternative with acceptable morbidity and complication rates and sustained long-term clinical outcomes.^{33,34,70}

KEY POINTS

- Osteoporosis is defined as a BMD of 2.5 or more standard deviations below the peak bone mass for young adults (T-score \leq 2.5) on a DEXA scan.
- Patients with osteoporosis present higher risks for complications after deformity surgery. Bone quality of the spine should play an important role in the planning of surgical intervention for spinal deformities.
- Early complications of spinal instrumentation in osteoporotic patients include pedicle fractures and compression fractures. Late complications include pseudarthrosis with instrumentation failure, adjacent level disc degeneration, compression fractures, and progressive kyphosis.
- The role of osteoporosis in the etiology of adult degenerative deformity and adolescent idiopathic scoliosis is controversial.
- Biposphonates are the mainstay of treatment for osteoporosis. Vitamin D and calcium supplementa-

tion offer limited benefit but are largely used as they are cheap and relatively harmless. Parathyroid hormone has been shown to improve bone quality and could be considered preoperatively and postoperatively.

- Several adjuvant techniques, which have been shown to significantly increase the rates of obtaining a successful fusion, have been employed in deformity surgery in patients with osteoporosis, such as cement augmentation, special screws designed to osteoporotic bones, bone morphogenetic protein and extension of the fusion to the pelvis. Intraoperative navigation can assist in the placement of spinal instrumentation to insure that pelvic screws are placed in an optimal position, ultimately reducing the risks of hardware failure.
- In patients with complex deformity and significant impairment of their quality of life, several studies have demonstrated that a major surgical intervention provides a safe “last resort” therapeutic alternative. In the setting of osteoporosis, due to the higher risks of complications, objective informations regarding the risk/benefit ratio of a major surgical procedure in relation to the natural history of the disease should be clearly provided to the patient and his/her family, so that they may perform a conscious and responsible decision.

INTRODUCTION

Primary spinal tumors are rare, with an estimated incidence of roughly 2.5–8.5 per 100,000 people per year.¹ They are generally more common in men, with some tumor types displaying a 2:1 incidence in men compared with women. Secondary, or metastatic, spinal tumors encompass >95% of all spinal tumors.² A majority of primary bony spinal tumors are benign, but a small percentage are malignant. The most common benign primary bony spinal tumors are giant cell tumors (GCTs), aneurismal bone cysts (ABCs), osteoid osteoma, osteblastoma, hemangioma, osteochondroma, and eosinophilic granuloma (otherwise known as Langerhans cell histiocytosis). The most common malignant primary bony spinal tumors are plasmacytoma (often a singular precursor to multiple myeloma), chondrosarcoma, osteosarcoma, chordoma, and Ewing tumors.³

The excision of bony spinal tumors is inherently more challenging than that of musculoskeletal tumors of the appendicular skeleton due to the anatomy of the spine and the need to preserve the spinal cord, its blood supply, nerve roots, and in the cervical spine—the vertebral arteries. As such, tumors of the spine are relatively unique in that their treatment falls into an area of medicine in which many different fields of practice overlap, including orthopedic surgery, radiology, neurosurgery, oncology, pathology, interventional radiology, and radiation oncology.

Whenever possible, treatment plans should be planned and carried out by coordinated, multidisciplinary teams to minimize the potential for complications, such as delayed or misdiagnosis, as well as incomplete or oncologically inappropriate resection that may lead to local or metastatic recurrence.

PATIENT PRESENTATION

The most common complaints of patients with spinal neoplasms, whether benign or malignant, are axial back pain or less commonly radicular pain, particularly at night or at rest, and progressive neurologic deficit. Suspicion for spinal tumors should be heightened when the patient has also suffered from unexplained weight loss and fevers. Rapid onset and progression of neurologic deficits are more typical of pathologic fractures or fast-growing malignant tumors, but even benign tumors can be locally aggressive and may cause rapid neurologic deterioration. Particularly when neurologic deficits progress slowly, there is often a prolonged delay between the onset and diagnosis of spinal tumors. This is compounded by the fact that there is often a delay between the onset of symptoms and the appearance of radiographic signs of disease, which may prevent a patient's case from being referred from the primary care level to that of a specialist that is more thoroughly equipped to effectively diagnose and treat the disease.

DIAGNOSIS

When a spinal neoplastic lesion is suspected, it must be fully imaged with X-rays, computed tomography (CT), and magnetic resonance imaging (MRI) in order to narrow the differential diagnosis. Plain radiographs are often demonstrative of primary bony spinal lesions, and occasionally diagnostic in and of themselves. Certain primary bony spinal tumors, such as osteoid osteoma or aneurysmal bone cysts, have characteristic findings on X-rays and high-quality CT scan that may not be evident if the clinician relies simply on an MRI. The diagnostic criteria of an osteoid osteoma will be discussed later in this chapter. Clinicians should be familiar with them in order to avoid excessive, unnecessary testing, and delays in diagnosis. A tissue biopsy (fine needle aspiration, core biopsy, incisional or excisional biopsy), however, is nearly always needed to make a definitive diagnosis. To identify any possible distant pathology, a full systemic workup, including CT scan of the chest, abdomen, and pelvis; nuclear medicine bone scan; and a positron emission tomography scan when available should be performed once a primary bony spinal tumor is diagnosed or highly suspected. Whenever possible, the clinician or clinical team who will be handling a patient's definitive treatment should be the ones to perform any diagnostic biopsy, in an attempt to reduce metastatic or recurrent disease as a result of inadvertent, untreated seeding of the biopsy track, or unnecessary violation of multiple fascial planes. In one study of patients who underwent en bloc tumor excision at a second institution after a failed primary attempt elsewhere, 72% suffered major complications compared to only 20% of patients whose investigation and primary surgical treatment were coordinated in a single institution. Furthermore, at an average follow-up of 37 months, 40% of the patients who required a repeat attempt at wide resection had local recurrence of their tumors, compared to only 16% of the new presentation group.⁴

STAGING/TREATMENT PLANNING

Once a definitive diagnosis has been established, oncologic and surgical staging of the tumor is necessary for the planning of treatment. The Enneking staging system,⁵ originally developed in the 1980s for the staging of appendicular musculoskeletal tumors, stages tumors from an oncologic perspective. Benign tumors are divided into S1 (latent, inactive), S2 (active), and S3 (aggressive)

(Figs. 117.1A to C), while localized malignant tumors are divided into stages 1 and 2 for low or high grade, respectively, in addition to A or B for intra- or extra-compartmental extension (Figs. 117.1D to G). Stage 3 is reserved for metastatic lesions. This system helps elucidate whether surgery may be inappropriate, curative, or just palliative, and what surgical margin may be necessary: intralesional, marginal, or wide.

Weinstein, Boriani, and Biagini later developed the WBB⁶ system (Figs. 117.1A to G) specifically for primary bony spinal tumors to aid surgical planning. In this schema, the vertebra is divided into 12 numerical zones radiating in a clockwise fashion starting from the spinous process, as well as 5 progressively deeper layers, labeled A–E, from paravertebral to dural involvement. A tumor may also be labeled “F” if it involves the spinal foramina. Longitudinal

Figs. 117.1A to G: Enneking staging for spinal tumor. (A) Inactive benign, encapsulated tumor (Stage I benign tumor), (B) active benign, encapsulated tumor (Stage II benign tumor), (C) aggressive benign tumor with expansion of the capsule (Stage III benign tumor), (D) encapsulated malignant tumor within the vertebra (Stage IA), (E) malignant tumor with extraskelatal expansion (Stage IB), (F) encapsulated malignant tumor within the vertebra with multiple infiltrative lesions in the pseudocapsule (Stage IIA), and (G) the pseudocapsule is infiltrated by aggressive tumor, which is growing outside the vertebra (Stage IIB). An island of tumor can be found far from the main tumoral mass.

Fig. 117.2: Weinstein-Boriani-Biagini surgical staging system of spine tumors. In the transverse plane, the vertebra is divided into 12 radiating zones (numbered 1–12 in a clockwise order starting from left side of the spinous process). There are five layers from the paravertebral area to the intradural space. The tumor is identified by the numbers of the zones and the letters of the layers involved, and the vertebrae of involvement.

extent is denoted by indicating which specific vertebrae are involved (Fig. 117.2).

The WBB system takes into account the unique anatomy of the spinal column and the need to preserve the spinal cord while also helping to dictate surgical approach. Tomita et al. studied numerous major and minor prognostic factors for spinal tumors to describe a system consists of seven types (Figs. 117.3A to G), which is based on the most common patterns of longitudinal and horizontal spread of the tumor.

TREATMENT OPTIONS

Surgery

Benign primary spinal tumors, such as hemangiomas, are on occasion incidental findings and do not require treatment so long as they remain asymptomatic. However, when primary bony spinal tumors are the cause of significant

Figs. 117.3A to G: Tomita primary surgical classification of vertebral tumors classification based on the most common patterns of longitudinal and horizontal spread of the tumor. (A) type 1—localized inside the body or lamina, (B) type 2—lesion extends into the pedicle, (C) type 3—lesion extends throughout the vertebra, (D) type 4—there is epidural extension, (E) type 5—paraspinal area is affected, (F) type 6 and (G) type 7—lesions show multilevel involvement.

pain, progressive neurologic deficit, or threaten spinal stability, treatment is warranted. The goals of treatment are alleviation of pain, decompression of neural elements, and restoration or maintenance of spinal stability, as well as cure or palliation when cure is not deemed feasible.⁶

Tumors may be surgically excised piecemeal via curettage, otherwise known as an intralesional excision, or “en bloc,” meaning in one intact piece. En bloc excisions are generally performed via vertebrectomy (otherwise known as spondylectomy), sagittal resection, or resection of the posterior arch, depending on the oncologic and surgical staging of the tumor. Vertebrectomy (Figs. 117.4A and B) refers to the removal of the entire vertebral body, often with portions of the posterior elements. Vertebrectomy allows for appropriate oncologic margins when the tumor originates in the center of vertebral body and involves more than one pedicle (WBB zone 4–8 or 5–9 or Tomita types 1–6). Sagittal resection (Figs. 117.5A and B) is suitable for tumor in an

Figs. 117.4A and B: Vertebrectomy. (A) En bloc excision of a tumor occurring at the vertebral body can be performed if at least one pedicle is free from tumor. (B) A posterior stage is performed to remove the posterior elements, cut the longitudinal ligament, and separate the anterior surface of the dura from the posterior wall then the anterior approach is mandatory.

eccentric portion (WBB zones 3-5 or 8-10 or Tomita type 1, anatomic site 1 that is eccentrically located). An en bloc excision of the posterior arch (Figs. 117.6A and B) is performed when a tumor involves the posterior arch and does not involve the pedicle (WBB zones 10-3 or Tomita type 1, anatomic site 3). Instrumentation is often needed to prevent progressive deformity.

En bloc excisions may be marginal, with excision along the tumor's border or pseudocapsule, or wide, wherein the tumor is removed with at least 2 mm of healthy surrounding

tissue. The term "radical" excision should be avoided when discussing spinal tumors, as a radical vertebrectomy would technically necessitate the sectioning of the spinal cord above and below the level of excision, which in practical terms is rarely, if ever, possible.⁷ If a biopsy is performed before definitive surgical treatment, an effort should be made to clearly mark the soft tissue along the biopsy track so that it may be excised during surgery to prevent seeding of the track with tumor cells and later recurrence. While en bloc excisions with wide margins have lower rates of tumor recurrence, they are typically long operations requiring high operator skill and are associated with significant morbidity and mortality.

Following intralesional excision, adjunctive sclerosing agents, such as liquid nitrogen or alcohol, are at certain times utilized in an attempt to eradicate remaining marginal tumor cells and decrease local recurrence rates. Bone grafting or bone cement may be used to fill voids left by tumor excision or by destructive, lytic lesions in order to reduce pain, and improve vertebral stability. However, if autologous bone grafting is to be performed, it is best to access the harvest site via a separate operative setup and incision to reduce the likelihood of iatrogenically spreading the tumor.

Lytic tumors may lead to vertebral collapse and spinal instability and create postexcisional gaps following intralesional and especially en bloc excisions. As such, a combination of bone grafting and spinal instrumentation is often necessary to maintain or restore spinal instability.

Percutaneous Therapy

Some primary bony spinal tumors may be effectively treated or even cured percutaneously, such as osteoid osteomas via laser photocoagulation or radiofrequency ablation (RFA) or aneurysmal bone cysts via percutaneous intral- esional injection of a sclerosing agent such as alcohol.⁸ Percutaneous arterial embolization has been effectively used to limit the extent of intraoperative bleeding during the excision of highly vascularized tumors, and may even be curative for aneurysmal bone cysts. Percutaneous vertebroplasty or kyphoplasty, in which cement is percutaneously injected into the vertebra, can be a useful palliative procedure for patients who have painful and/or destabilizing lytic lesions that are unamenable to surgery.

Radiation Therapy

Radiation therapy is an effective tool in the treatment of fast-growing tumors, as it essentially works by damaging DNA, which prevents cell replication and causes cell death. In general, the more benign primary spinal tumors such as osteoid osteoma, osteoblastoma, and osteochondroma have poor response rates to radiation therapy. Furthermore, some benign primary tumors such as GCTs and chondroblastomas are known to rarely undergo transformation into malignant sarcomas following radiation therapy. Regardless, adjuvant, or postoperative, radiation is sometimes used following the excision of benign tumors in an attempt to kill any remaining tumor cells in the marginal tissues. Radiation therapy is an integral component in the treatment of many malignant primary spinal tumors. It is often used as a neoadjuvant (or preoperative) treatment, particularly in cases of osteosarcoma or Ewing's tumor, as this can decrease tumor bulk and facilitate surgical excision. Despite high rates of radiation resistance seen in chordoma and chondrosarcoma, adjuvant radiotherapy is routinely administered to surgical margins following the excision of malignant primary tumors.

Studies have shown that effective local control can be achieved following surgical excision of sarcomas in the extremities with a 60 Gy dose of postoperative radiation therapy. Doses of 70 Gy are typically given when there is gross evidence of residual tumor. The difficulty of administering radiation therapy in the spine, however, is that the spinal cord can typically tolerate no more than a cumulative dose of 50 Gy before patients experience radiation-induced myelopathy.⁹ As such, traditional external photon beam radiation can be extremely challenging to deliver. The fields of radiation and interventional oncology have

responded by developing several advanced methods of delivering effective doses of radiation to highly specific targets, such as intraoperative radiation therapy and brachytherapy, proton beam therapy, and high-dose conformal photon therapy.

Chemotherapy

Chemotherapy is of limited benefit in most bony spinal tumors, with the exception of osteogenic sarcomas, which has been shown to respond to combinations of several conventional chemotherapeutic agents, such as cisplatin, doxorubicin, and methotrexate, and chordomas, which have recently demonstrated sensitivities to angiogenesis and tyrosine kinase inhibitors such as imatinib (Gleevec), sunitinib (Sutent), erlotinib, and gefitinib.

Prognosis

Outcomes data on primary spinal malignancies are limited because of the rarity of the tumors and the studies available are mostly small case series of various types of tumor. However, the National Cancer Institute's SEER (Surveillance Epidemiology and End Results)³ registry helps to identify patients with primary spinal malignancies. Data from this registry have concluded that distant metastasis is a poor prognostic factor and is associated with a three- to fourfold decrease survival rate in patients with osteosarcoma, Ewing sarcoma (EWS), chondrosarcoma, and chordoma. Other independent factors that decreased survival time in osteosarcoma, chondrosarcoma, and chordoma are advanced age and increased extent of tumor invasion, including distal site metastasis.¹⁰

BENIGN TUMORS

Bone Island (Enostosis)

An enostosis or bone island represents a focus of mature compact (cortical) bone within the cancellous bone (spongiosa). Bone islands are probably congenital or developmental in origin and reflect hamartomatous lesions or a failure of resorption during endochondral ossification. Bone islands are typically asymptomatic and found incidentally. Although enostoses most commonly occur in the pelvis, femur or other long bones, they can occasionally be found in the spine. Plain radiographs show a homogeneously dense, sclerotic focus in the cancellous bone with distinctive radiating streaks, so called "thorny radiations" that blend with the trabeculae of the host bone, creating

a feathered or brush-like border. On CT scan, a bone island appears as a low-attenuation focus. On MRI, the lesion shows low signal intensity, like cortical bone. Bone scan may be used to differentiate bone islands from other aggressive tumors since they are usually a “cold” lesion. However, scintigraphically active or “hot” bone islands have been reported with histological confirmation.¹¹ Physicians should be cautioned to not rely solely on a bone scan, but rather on an individual’s clinical presentation and radiographic findings. A scintigraphically “hot” bone island demands close observation and follow-up imaging studies. Differential diagnoses include blastic lesions or tumors: osteosarcoma, metastasis from prostate cancer, ganglion cyst, or an ongoing process of fracture healing. Histopathological finding reveals normal, lamellar bone with normal architecture and no cartilage or enchondral ossification. Once the diagnosis of enostosis has been made, biopsy is typically not necessary. Lesions can be observed without treatment.

Osteoid Osteoma

An osteoid osteoma is a painful, benign lesion that typically occurs in childhood and adolescence. The average age of presentation is 19 years, with >80% of the patients presenting before the age of 30 years.¹² There is a predilection for males [male:female (M:F), 2–4:1]. It is relatively common, making up approximately 10% of all benign bone tumors.¹³ The classical presentation is a patient with nocturnal pain that wakes them from sleep and is relieved by salicylates (e.g. Aspirin). Osteoid osteoma in the spine is the classical cause of painful scoliosis, seen in 75% of patients with painful scoliosis (Figs. 117.7A and B).¹⁴ Plain radiographs reveal reactive sclerosis (Fig. 117.8A). Most osteoid osteomas occur in long bones of the extremities, but essentially any bone may be involved. Osteoid osteoma of the spine accounts for 10% of all cases, distributed approximately as follows: lumbar 59%, cervical 27%, thoracic 12%, and sacrum 2%. Osteoid osteoma can occur anywhere within the bone, including cortex, medulla or in subperiosteal bone. The nidus is usually <2 cm in diameter, and clearly seen on CT, intraoperative photograph and histology (Figs. 117.8B to D). It may present with a central mineralization. The nidus releases prostaglandins, which result in pain (via Cox-1 and Cox-2). Pathological findings are a nidus of interlacing osteoid and woven bone, seen as interconnecting trabeculae or sheets with osteoblastic rimming (Fig. 117.8E). The tissue surrounding woven bone is composed of loose fibrovascular tissue with prominent osteoclasts (Fig. 117.8F).

Figs. 117.7A and B: (A) Posteroanterior radiograph of thoracolumbar spine shows levoconvex (12.5°) lumbar scoliosis with convexity toward right side and expansile lytic lesion at the region of left L4 pedicle (arrow). (B) 99 m-TcMDP bone scan showing focally increased uptake at corresponding L4 vertebra.

The lesion is benign and the treatment has traditionally been with marginal surgical resection. Surgical resection has been difficult because of the inability to locate the nidus intraoperatively. Percutaneous RFA under CT guidance has increased in popularity of late. Vanderschueren et al. reported a 79% and 96% cure rate after the first and second RFA treatment, respectively,¹⁵ although spinal deformity persisted in three of seven patients (47%) after treatment.¹⁶ Rehnitz et al.¹⁷ reported long-term (mean 38.5 months follow-up) satisfaction regarding return to normal activity and pain relief following RFA ablation. With three-dimensional CT preoperative planning and thermal protection techniques, RFA is considered safe and has a low rate of complications. Rarely reported RFA cannula breaks can lead to a short hospital stay.¹⁸ Video-assisted thoracoscopic surgery (VATS) guided by navigation system (VATS-NAV) has recently been performed in spinal osteoid osteoma to facilitate precise complete excision through a minimal approach and yield tissue pathology that RFA could not provide.¹⁹

En bloc excision has a role in patients with a fixed spinal deformity, with neurological compression, or who have failed RFA or have a tumor in a dangerous zone for RFA. Excision is a curative treatment and brings immediate relief after the operation. Spinal instrumentation and arthrodesis are recommended for cases in which resection may lead to spinal instability.

There is growing evidence that osteoid osteoma may fully resolve spontaneously over time. Selected patients

have been successfully treated with nonsteroidal anti-inflammatory drugs (NSAIDs) in an average of 33 months.²⁰ However, the side effects of prolonged NSAID use, such as gastrointestinal bleeding, should be considered. Moreover, associated spinal deformity such as scoliosis will typically resolve spontaneously if the nidus is surgically resected within 15 months from the onset of deformity.¹⁴

Osteoblastoma

Osteoblastoma is a benign bone-forming tumor that is pathologically similar to osteoid osteoma except in that it is much larger and more aggressive in behavior. Osteoblastoma is rare, accounting for 1–3% of all benign bone tumors. Patients usually present in the second to the third decades of life. There is a male predilection with an M:F ratio of 2.5:1. The average age at presentation is 20–24 years, but

the age of onset has been reported to range from 1 to 72 years.²¹ Patients typically present with dull pain that gradually worsens. Symptoms are typically not worse at night and respond poorly to NSAIDs. Painful scoliosis is the common symptom, but is reported less frequently than in osteoid osteoma. Neurological deficits are reported in 32% of cases. For spinal osteoblastoma, 32–46% occur in the thoracic and lumbar spine, 9–39% in the cervical spine and 17% in the sacrum. It often involves the posterior column and may extend to the vertebral body in larger lesions.²²

Radiographic features include a wide range of patterns. Lesions are >2 cm in size, predominantly lytic with a sclerotic rim, and expansile (Figs. 117.9A to D), sometime present with internal calcification. These lesions are very often associated with hypervascularity. Histologically, osteoblastoma is similar to osteoid osteoma, with prominent osteoblasts that produce woven bone (Figs. 117.9E and F).

Figs. 117.8A to E1

Figs. 117.8A to F: Osteoid osteoma of the thoracic spine. (A) Anteroposterior radiograph showing thoracolumbar scoliosis. (B) Anterior view 99 m-TcMDP bone scan showing the area of increased tracer uptake is the left portion of T10 vertebra. (C) Computed tomography scan axial view showing the nidus (1 cm) can be seen at the lamina, with reactive sclerosis of the pars interarticularis and superior articular process and marrow edema extending up to the pedicle. (D) Intraoperative finding showing hypersclerosis of the tumor on the left posterior arch. (E) Hematoxylin and eosin showing the characteristic anatomosing bony trabeculae and osteoblastic rimming. (F) Osteocalcin immunohistochemistry showing positivity of osteocalcin immunohistochemistry reassures an osteoblast-rich lesion.

Figs. 117.9A and B

Figs. 117.9C to F

Figs. 117.9A to F: Osteoblastoma of the lumbar spine. (A) Sagittal magnetic resonance T1 and T2 weighted showing the intermediate signal activity of the osteoblastoma in the L4 vertebral body with minimal protrusion out into the vertebral canal posteriorly. Note the very bright high-signal aneurysmal component to the osteoblastoma extending out into the paraspinal muscle. (B) and (C) Serial axial computed tomography showing the lesion locates in the lamina and pars interarticularis, extends to superior articular process, and erodes spinal canal. (D) Gross pathology; shows well-defined, red to tan tumor mass with hemorrhagic areas. The compact tissue is granular and friable. Central nidus is >2 cm. (E) and (F). Hematoxylin and eosin showing irregular spicules of mineralized bone and eosinophilic osteoid rimmed by osteoblasts.

About 10–15% of osteoblastomas are associated with an aneurysmal bone cyst.

Wide en bloc surgical excision is the treatment of choice for osteoblastoma in cases of very painful lesions and lesions increasing size that can cause bony destruction, neurological compromise, and spinal instability. Pre-operative embolization is commonly performed to reduce the risk of intraoperative bleeding. If en bloc resection cannot be achieved due to limitations of the anatomic location, intralesional curettage and cementation or bone grafting may be performed.²³ Recurrence rates are reported to be 10–24%.²⁴ Intralesional excision has proven to be effective in Enneking stage 2 lesions and en bloc

resection in stage 3 lesions. Incompletion of the resection demonstrated higher recurrence rates.²³ Poor outcomes are generally due to malignant transformation to sarcoma, spinal cord compression and spinal cord necrosis.

Osteochondroma

Osteochondromas are relatively common in general, making up 9.2% of all primary bone tumors that are surgically treated. However, only 2.5% of all osteochondromas occur in the spine. They are cartilage-capped bony growths that typically occur in the cervical or upper thoracic spine. They are most often painless, but can be a source of pain, or very rarely spinal cord or nerve root impingement.²⁵

These tumors consist of expansile growths of cartilage-capped cortical bone with underlying medullary bone, with both types of bone being contiguous with their normal adjacent counterparts. Histologically, the tumor components are identical to those of normal bone. There is an M:F predominance of 2:1.^{26,27}

Approximately, 1% of osteochondromas will eventually undergo malignant transformation. If such a transformation is identified on tissue biopsy, or the patient is suffering from severe pain or neurologic deficit, complete surgical resection without neoadjuvant or adjuvant therapy is the treatment of choice.

Aneurysmal Bone Cyst

An ABC is a benign cystic lesion of the bone, the etiology of which is controversial. Features that lend weight to the theory that ABCs form as a reactive process include regression after removal and occurrence after fracture. However, the notion to categorize ABCs as a neoplastic disease is the discovery of the USP6 fusion gene (Tre2-oncogene) in ABCs.²⁸ The function of USP6 is still poorly understood but recent evidence has shown that USP6 is involved in endocytic trafficking and operates in a pathway that has been linked to mitogenic signaling and invasive behavior.²⁹ The lesions constitute 1.4% of all primary bone tumors and 15% of all primary spine tumors. Aneurysmal bone cysts are primarily seen in the second decade of life, with 20% occurring in patients <20 years old and a slight predominance in females. ABCs consists of blood-filled spaces that are separated by connective tissue containing trabeculae of bone or osteoid tissue and osteoclast giant cells. Out of all cases of ABC, 20–30% are located in the spine, especially the posterior elements, with extension to the vertebral body in 40% of cases. Nearly 70% of ABCs occur in the thoracolumbar region and 30–40% are associated with multiple, contiguous levels.³⁰

Plain films will typically demonstrate an expansile osteolytic lesion with a sharply defined border and thin sclerotic margins. Computed tomography reveals a characteristic multilocular lesion with cortical expansion. Magnetic resonance imaging shows multilocular lesions with fluid-fluid levels on T2 weighted images. Although these findings are highly indicative of ABCs, GCT, and telangiectatic osteosarcoma should be included in the differential diagnosis. Although they are often primary, one third of ABCs occur secondarily after other benign bone tumors, such as chondroblastoma, fibrous dysplasia, or GCT.

Histological findings are small blood-filled spaces separated by septae. This consists of spindle-cell fibrous tissue and multinucleated osteoclast-like giant cells with thin trabeculae of woven lamellar bone without an endothelial lining and thin wall blood vessels.

Aneurysmal bone cysts do not spontaneously resolve and surgical intervention is needed. Minimally invasive approaches consisting of selective arterial embolization have shown to promote regression and recalcification and provide symptomatic relief.³¹ Selected cases included patients who had intact lesion and without severe instability or neurological compromise.

In more aggressive lesion, surgical removal of the tumor is indicated. Intralesional curettage resulted in recurrent rate of 10–31%,^{30,32} while complete marginal resection showed recurrent rate of 10%.^{33,34} However, marginal or wide resection may not be possible due to the location of the lesion and possible postexcisional spinal instability. Preoperative embolization is suggested to reduce intraoperative blood loss in relatively large lesions. Adjuvants such as phenol, liquid nitrogen,³⁵ argon beam electrocautery,³⁶ and polymethyl methacrylate (PMMA)³⁷ may significantly lower rates of recurrence. The percutaneous injection of fibrosing agents has been used either alone or in conjunction with surgery, but the technique has been largely abandoned due to high rates of complications, such as pulmonary embolus, aseptic fistulization and transient inflammatory reaction.³⁸ Radiotherapy has been done in inoperable case; however, it is associated with a high rate of recurrence (31%)³⁹ and a risk of transforming into a sarcoma.

Giant Cell Tumor of Bone

Giant cell tumors comprise 18–23% of benign bone neoplasms and 4–9.5% of all bone neoplasms. Of all GCTs, approximately 2–5% occur in the spine.⁴⁰ Giant cell tumors are most often found in the vertebral body, with primary sites equally distributed between cervical, thoracic, and lumbar regions.⁴¹ They almost always occur after the growth plate has closed and are therefore typically seen in early adulthood, with 80% reported between the ages of 20 and 30 years. Females are affected with more frequency. Giant cell tumors are believed to result from an overexpression of the RANKL signaling pathway that leads to an uncontrolled production of osteoclasts.⁴² Back pain is the most common presentation complaint and may be accompanied by radicular pain. Spinal cord compression

and neurological deficits may be present in up to 50% of cases.⁴¹

Radiographs reveal an expansile, osteolytic lesion with a sclerotic rim.⁴³ Computed tomography and MRI provide a higher level of anatomical detail and demonstrate any invasion into adjacent tissue. Chest X-ray or CT is required to evaluate for rare cases of pulmonary metastasis. On gross pathology, GCTs are made up of yellowish-tan, soft, and friable tissue. Histologically, GCTs are composed of two cell types—osteoclast-type giant cells and spindle cells that are considered the active tumor cell. Giant cell tumors frequently coexist with aneurysmal bone cysts, resulting from numerous thin wall vascular channels that may cause hemorrhages.

En bloc excision with a wide margin is recommended for GCTs of the thoracic and lumbar spine or Enneking stage 3 tumors,⁴⁴ although a wide margin may be difficult to achieve and is associated with greater morbidity than intralesional or marginal excisions. In the cervical and sacral regions where a wide margin may be technically impossible, treatment is typically intralesional curettage and packing with bone graft or PMMA bone cement. Intralesional resection may provide adequate control with Enneking stage 2 tumors.⁴⁴ En bloc excision has a local recurrence rate of 20–25%⁴³ while intralesional curettage has shown recurrence rates of 40–60%. There were more frequent recurrences in patients who had a lesion involving both the arch and body of the vertebra.⁴¹ Intraoperative adjuncts such as cryotherapy, cauterization or chemical treatment such as phenol and hydrogen peroxide have lowered the recurrence rates to 2.5–10%.⁴⁵ However, Ruggieri et al. reported that adjuvants had no influence on local recurrence for sacral GCT.⁴⁶ Adequate removal of the tumor by curette and high-speed burr is the most important factor to achieve good outcomes.⁴⁷ Age <25 years⁴⁴ and >45 years⁴⁸ has been associated with shorter relapse-free survival in spinal GCTs.

Single or multiple uses of intravenous bisphosphonates with subsequent complete surgical resection could reduce the recurrence rate of GCT.^{49–51} In small series, the direct RANKL inhibitor denosumab has shown great promise in its ability to decrease GCT size and induce new bone formation among patients with unresectable GCTs.⁵² However, further randomized trials with higher enrollment and long-term follow-up are needed before this therapy becomes mainstream.⁵³

Hemangioma

Often discovered incidentally, hemangioma, a type of vascular abnormality, may develop along the axial spine. While <5% of patients with a spinal hemangiomas develop symptoms, they may be the cause of significant neck or back pain when the growth causes spinal cord or nerve root compression, compression fractures, or rarely an epidural hemorrhage.² If a spinal hemangioma is causing pain alone, with no neurologic deficit, analgesia can typically be achieved without undergoing surgery. However, if an expansile hemangioma causes progressive neurologic deficit, surgical decompression is recommended. Expansion of hemangiomas to the point of causing spinal cord compression has been reported during pregnancy.

Within the involved vertebrae, plain radiography and CT typically will demonstrate coarsened trabeculae with a characteristic “honeycombed appearance,” while MRI typically demonstrates a soft tissue component.

When intractable pain or neurologic deficit is present due to a spinal hemangioma, the anatomic location is amenable to excision, and the patient is a suitable surgical candidate from a medical perspective. The ideal treatment is laminectomy followed by adjuvant radiation therapy, which has been shown to yield a 93% rate of neurologic recovery without recurrent symptoms in a 52-month follow-up period, while laminectomy alone resulted in local tumor control rates of 70–80%.^{54,55} Percutaneous vertebroplasty should be considered in patients who have symptomatic hemangiomas who are not good surgical candidates, as this less invasive treatment has been shown to result in excellent pain relief.⁵⁶

Eosinophilic Granuloma (Langerhans Cell Histiocytosis)

Eosinophilic granulomas are the bony tumors associated with Langerhans cell histiocytosis. They are most commonly found in children <10 years of age, and vertebral involvement is found in 10–15% of these cases.²⁵ They are typically benign, destructive lesions caused by a proliferation of histiocytes. These tumors are most often self-limiting, and occasionally affect multiple spinal levels. Usually found incidentally, they are rarely the cause of significant pain.

Radiographically, eosinophilic granulomas are identified as destructive, lytic lesions with clearly demarcated borders and no soft tissue involvement. Adjacent disc spaces are well preserved. These lesions must be differentiated

from other lytic lesions, such as infections or malignancies.

These lesions will typically resolve over time, so conservative treatment with bracing and limiting activity is the best initial approach. However, if lytic destruction causes vertebral collapse and neurologic compromise, surgical decompression and arthrodesis may be required.

MALIGNANT TUMORS

Primary malignant tumors of the spine account for <5% of primary bone tumors.³ The most common bone sarcomas are osteosarcoma, chondrosarcoma, EWS, chordoma, and malignant fibrous histiocytoma/fibrosarcoma.³ Surgery is the mainstay of treatment, although the anatomy of the bony spine and its relation to the spinal cord often limits complete surgical resection with wide margin. Chemotherapy and radiation therapy have shown variable effects on these tumors. With recent advances in surgical techniques and development of new chemotherapy, local control and patient survival are improving.

Osteosarcoma

Spinal osteosarcoma accounts for 3.6–14.5% of primary spinal tumors^{57,58} and 1.2–3% of all osteosarcomas.^{59,60} It occurs more commonly in older age groups than osteosarcoma of the extremities, at a mean age of diagnosis of 38 years.⁶⁰ There is a slight predominance in females over males. Eighty percent of vertebral osteosarcomas develop in the posterior elements. Pain in the area of involvement is the first symptom in most patients. Fifty to seventy percent of patients display neurological symptoms.⁶⁰

Plain radiographs show cortical destruction and soft tissue mass formation. Osteoid matrix can be seen in most cases. Lesions may show osteolytic or osteoblastic features. Magnetic resonance imaging is superior for demonstrating tumor extent within the bone marrow and any associated soft tissue masses, including the delineation of epidural tumor extension.

Complete resection with neoadjuvant and adjuvant chemotherapy is the mainstay of treatment. Common therapeutic medications include cisplatin, methotrexate, and doxorubicin.

Based on data from the SEER registry,³ median survival in patients with an isolated lesion of primary osteosarcoma of the spine was 18 months compared to 7 months in those who present with distant metastasis. Ozaki et al.³⁷ studied 12 patients with spinal osteosarcoma and showed overall

survival had decreased in patients with distant metastases, tumors larger than 10 cm, and sacral tumors. Wide or marginal excision of the tumor improves survival. Shives et al.⁶⁰ showed only 1 in 30 patients survived for > 10 months. The prognosis is worse when compared to appendicular tumors because of the increased challenges to performing wide excision without injury to the surrounding vital structures. Patient outcomes are difficult to compare due to the use of different treatment protocols of varying chemotherapy and resection techniques in different treatment centers. Bisphosphonates have been used in conjunction with chemotherapy in osteosarcoma of the extremities and showed no significant improvement in 5-year and overall survival (72%, 93%), but may improve the durability of instrumentation.⁶¹ Mifamurtide, an immune-stimulant muramyl tripeptide phosphatidylethanolamine, was used in clinical trials of 677 patients in adjunct with chemotherapy and showed an improved overall survival, but did not reach statistical significance in event-free survival.^{62,63} Another immunotherapeutic agent that is being pursued for pulmonary metastatic disease is inhalation of aerosolized granulocyte macrophage colony-stimulating factor. However, a benefit could not be shown in a trial of 43 patients with pulmonary relapse and it should not be considered a standard therapy.⁶⁴

Chondrosarcoma

Chondrosarcoma is a malignant cartilaginous tumor that accounts for 20–27% of all malignant bone tumors. Typical presentation is in the 4th and 5th decades. There is a slight male predominance. Male:female is 1.5–2:1 for chondrosarcoma in general, and spinal chondrosarcoma has an even greater male predominance of 2–4:1. Chondrosarcoma occurs in the spine in approximately 2–12% of cases,⁶⁵ affecting the thoracic spine the most (51%), followed by cervical (35%), and lumbar segments (14%).⁶⁶ Posterior elements and the vertebral body are affected in 45% of cases, the posterior elements alone in 40%, and the vertebral body alone in 15% of cases.⁶⁷ In general, the patient often presents with pain and a large mass at the time of diagnosis. About 50% of the patients present with neurological symptoms.⁶⁷

Radiographic findings of chondrosarcomas depend on the histological grading. Most low-grade tumors demonstrate lytic lesions on imaging, which may be difficult to differentiate from enchondroma. High-grade tumors demonstrate moth-eaten destruction with “ring and arc” (Figs. 117.10A and B) or popcorn calcification and

Figs. 117.10A to D: Chondrosarcoma of the spine. (A) Axial computed tomography scan showing a large mass arising from the vertebral body with cortical disruption and “ring and arc” calcifications. (B) Axial T2-weighted magnetic resonance showing a high-signal intensity lobulated mass with linear striations. (C) and (D) Photomicrograph (original magnification, x4 and x40, hematoxylin and eosin stain) showing a lobulation of cartilage tumor and resorption of the pre-existent bone trabecula (C) and low-to-moderate cellular atypia and mitotic activity, demonstrated by hypercellularity, binucleate cells, multiple cells in lacunae and atypical nuclei.

endosteal scalloping. Histological grading is the best predictor of the prognosis (Figs. 117.10C and D).

Chondrosarcomas are generally resistant to radio and chemotherapy; therefore, surgical removal is mandatory. Surgical treatment varies with grading and location; most grade 1 lesions can be treated by curettage (90% 5-year survival) and grade 2–3 with wide excision (29%, 5-year survival).

En bloc resection with a wide margin provides the best results regarding tumor control, with reported rates of recurrence of 3–8%.⁶⁸ In contrast, an intra-lesional curettage shows recurrence rates of up to 100%.^{68,69} Recurrence usually occurs within 3–5 years postoperatively, and earlier if a subtotal excision had been performed. Tumor-related

death is estimated at 12% in patients who undergo subtotal resection, compared to 42% in patients who undergo wide excision with a clear surgical margin.^{70,71} Although en bloc resection with clear margins is the ideal surgical management for spinal chondrosarcoma, the achievement of this may be technically challenging.

Chemotherapy has not proved to affect the outcome in spinal chondrosarcoma; therefore, its role is limited.^{68,69} The ineffectiveness of chemotherapy may be explained by tumor cells’ expression of multidrug resistance gene, P glycoprotein, large amounts of extracellular matrices in the tumors, or the poor vascularity and the low proliferation rates of chondrosarcomas.⁷² New chemotherapeutic agents such as histone deacetylase and aromatase

inhibitors are being studied in patients with unresectable or metastatic disease, but not enough data are currently available to determine whether these should be used on a more widespread basis.

Radiotherapy is frequently used in patients with surgically inadequate margins, but the overall survival in this group is lower than those who had margin-free en bloc excision without radiation.^{68,73}

Ewing Sarcoma

Ewing sarcoma is the second most common primary bone tumor, and typically occurs in children and adolescents between the ages of 10 and 20 years. It has a male predilection (M:F, 1.5:1). Ewing sarcoma is a small blue round cell tumor that is closely related to primitive neuroectodermal tumor (PNET), Askin tumors, and neuroepithelioma, all collectively are referred to as the Ewing sarcoma family of tumors. They share similarities in microscopic appearance and nonrandom t(11;12)(q24;q12) chromosome rearrangements. Up to 13% of EWS occurs in the spine that affects the sacrococcygeal (54%) and the lumbar regions (25%) most commonly.⁷⁴

Histological findings can be confused with osteomyelitis or hematologic malignancies, but EWS round cells are significantly larger than lymphocytes. Mitotic figures are present intermittently with karyopyknotic cells and apoptotic cells. Immunohistochemical staining of CD99 and vimentin is positive. CD99 positivity is due to the glycoprotein product of the *MIC2* gene, which is a common finding of EWS and PNET tumors. Ewing sarcoma does not produce matrix. It does, however, often produce large soft tissue masses that invade adjacent structures as well as the epidural space.⁶

Neoadjuvant chemotherapy with or without radiation is indicated for EWS. Ewing sarcoma responds more favorably than other bone sarcomas to radiation therapy, resulting in a nearly twofold increase in the 10-year survival rate since the 1980s. Survival prognoses of patients with EWS of the spine are slightly better than that of patients with spinal osteosarcoma. Patients have a median survival of 90 months in the case of an isolated lesion and 20 months in the case of metastatic disease. The overall 5-year survival rate is approximately 41%.⁷⁵

Chordoma

Originating from primitive remnants of the notochord, chordomas tend to be extremely difficult to resect due to

their proximity to neural elements. Data from the SEER registry indicate an annual incidence of 0.08 per 100,000 people. The M:F ratio is roughly 2:1, and patients tend to be >40 years of age.¹ Studies vary in reports of distribution in the axial skeleton; some studies show a propensity for distribution in the sacrococcygeal area and skull with a minority in the mobile spine, while others show a roughly even distribution between these three areas.^{76,77} Non-specific back pain is present in nearly all patients, with a radicular component in a minority. More than two-thirds of patients present with neurologic deficits. When the tumor arises in the sacrum, rectal dysfunction such as constipation, obstipation, or hemorrhoidal bleeding is common, and the tumor may be palpable on rectal examination.

Grossly, chordomas appear lobulated, gray, and partially translucent. Calcification may be identified by plain radiographs, but CT and MRI are most helpful in distinguishing bony and soft tissue extension, respectively. There is generally a tumor pseudocapsule. Histologically, chordomas are made up of “soap bubble” cells or “physaliferous cells” with vacuolated cytoplasm, as well as signet ring cells.

The optimal treatment for chordomas is wide en bloc resection, though this may be technically difficult to achieve as neural structures are typically involved. Regardless, a wide resection should be attempted while sparing as many nerve roots as possible. In the sacral area, sparing at least one of the S3 nerve roots may be sufficient to spare urinary and fecal continence. Local recurrence rates are high, particularly if the tumor’s pseudocapsule is violated, in which case local recurrence was identified in 64% of patients in one study.⁷⁸ Chordomas are generally not radiosensitive, and conventional external beam radiation is of limited or no value in their treatment, but newer modalities such as photon or proton beam therapy are now often employed as adjuvant therapy in an effort to reduce or delay recurrences. Radiotherapy is also offered for palliative, subjective pain control. As of yet, there is limited objective data as to the effectiveness of these strategies. Chordomas are similarly chemoresistant in general, but patients are often started on chemotherapeutic agents after receiving maximum radiation dosages or in cases of metastasis. Combinations of adriamycin-cisplatin or ifosfamide-adriamycin-platinum have shown some limited success. Recently, a number of investigators have seen good responses when treating chordomas with tyrosine kinase and angiogenesis pathway inhibitors, such as imatinib (Gleevec), erlotinib (Tarceva), and gefitinib (Irlissa).⁷⁹⁻⁸¹

More higher-enrollment, long-term studies are necessary to determine the long-term efficacy of these specific inhibitors.

Plasmacytoma/Multiple Myeloma

Solitary plasmacytomas of the spine and multiple myeloma may be thought of as two diseases on a spectrum, characterized by infiltration of the bone marrow by malignant plasma cells. Multiple myeloma is the second most common hematologic malignancy after non-Hodgkin's lymphoma, and is further characterized by multiple bony lesions as well as a marked reduction in normal immunoglobulins coupled with overabundant monoclonal antibodies in the serum, urine or both, in 99% of patients. Solitary plasmacytomas occasionally remain truly localized, and patients may remain disease-free after local radiation therapy, but in one half to two thirds of patients, plasmacytomas ultimately progress to multiple myeloma.^{1,82} These tumors cause osteolysis and when advanced may lead to vertebral collapse and subsequent myelopathy. In multiple myeloma, but rarely in the case of a truly solitary plasmacytoma, a monoclonal immunoglobulin spike is easily detected on serum or urine protein electrophoresis. Median survival in patients diagnosed with multiple myeloma is 28 months, while median survival of patients with solitary plasmacytoma exceeds 5 years.

Plasma cell tumors are highly radiosensitive. In the case of a solitary plasmacytoma, in the absence of spinal instability or neuropathy, local radiation alone is the treatment of choice, and this can be expected to achieve long-term control if not cure. Radiation therapy is also a key component when multiple myeloma is diagnosed, but bisphosphonates should be added to reduce excessive bone loss and pain. When large lytic lesions are obvious on imaging, patients with either diagnosis should be offered percutaneous vertebroplasty as this confers almost instantaneous pain relief in > 80% of patients.^{83,84} This may be offered even before radiotherapy, as it is immediately palliative for the patient and may prevent postradiation segmental instability or compression fractures. Instrumentation is generally necessary for stabilizing the spine if > 50% of the involved vertebral bodies have been eroded. In recent years, immunomodulatory treatments such as thalidomide and dexamethasone, proteasome inhibitor bortezomib (Velcade), and direct RANKL inhibitor denosumab have shown great promise in treating patients with multiple myeloma and further studies may lead to more widespread, efficacious treatments in the future.

Lymphoma

Hematologic malignancies originating from the spine most often occur in children. The patients may present with compression fractures in 5.7–16% of cases.⁸⁵ Tumors from both leukemia and lymphoma are most commonly found at the mid-thoracic or thoracolumbar level. Tumors can extend into the epidural space, resulting in neurological symptoms. Early diagnosis is mandatory because generally the prognosis is good when the proper treatment is initiated early. Treatment consists of chemotherapy with or without radiation, and surgery is generally not indicated.

Histological findings include densely packed lymphoid cells within the marrow space. Non-Hodgkin lymphoma presents as sheets of large B-cell with CD20 positivity. Hodgkin lymphoma has a heterogenous collection of hematopoietic cells, including Reed-Sternberg cells that are positive for CD15 and CD30.

SUMMARY

Primary bony spinal tumors, whether benign or malignant, are relatively rare. Nevertheless, whenever a patient presents with ongoing back pain, particularly if it is nocturnal, and/or the patient suffers from progressive neurologic deficits, the clinician must always rule out a spinal malignancy.

Definitive diagnosis and management of spinal tumors should be performed at a musculoskeletal oncology referral center. A cooperative, multidisciplinary team approach is essential to achieving the best outcomes. With the development of targeted therapies based on an improved understanding of the molecular pathology of spinal tumors, as well as with advances in diagnostic imaging, surgical technique, and percutaneous treatments, functional and survival outcomes of patients with spinal tumors may be expected to continue to improve in the future.

KEY POINTS

- Primary bony spinal tumors are rare, but deserve consideration in any patient presenting with back pain of uncertain etiology and must certainly be considered in any patient presenting with progressive neurologic deficits.
- Whenever possible, management of spinal tumors should be handled at all stages by a multidisciplinary team at a higher-level institution with extensive

experience in spinal oncology, as this has been shown to reduce rates of complications during treatment as well as tumor recurrence and overall survival statistics.

- All spinal tumor diagnoses should be confirmed by histology. Appropriate oncologic (Enneking) and surgical (WBB) staging must be assessed before deciding on a course of treatment.
- En bloc excision with a wide margin is typically the surgical treatment of choice, but is not always feasible given the unique anatomy of the spine and the need to retain neural structures.
- Percutaneous techniques such as RFA and vertebroplasty are being used ever more often for palliative, and at times definitive, curative treatment for bony spinal tumors.

INTRODUCTION

Sacral tumors are challenging neoplasms to treat, given their anatomic proximity to major vasculature and neural elements that control ambulation, sphincter control and sexual function. Primary sacral tumors are rare, representing only about 1% of all primary bone tumors and 7% of all primary spinal tumors.^{1,2} Because these tumors typically expand anteriorly and usually do not cause palpable posterior masses, they are often not discovered before reaching a large size and causing substantial osseous destruction.^{2,3} Although surgical resection and reconstruction techniques for sacral tumors have improved, new therapies are emerging and evidence-based algorithms for treating these tumors remain to be thoroughly developed and tested.

SACRAL ANATOMY

The adult sacrum consists of five fused vertebrae. Ossification of the intervertebral discs occurs in late adolescence through the third decade of life. The anterior surface of the sacrum is concave, and the posterior surface is convex; in addition, the sagittal tilt of the pelvis relative to the pelvis and acetabuli is variable. Understanding these unique anatomic features is necessary to evaluate radiographic studies of the sacrum in cases of suspected neoplasms and

plan surgical resections. In adults, the dural sac generally terminates at S2.⁴ There are four pairs of ventral and four pairs of dorsal foramina to allow the anterior and posterior divisions, respectively, of the sacral nerve roots to exit the sacral canal. Important for sacral resections, the piriformis muscles originate on the anterolateral aspect of the sacrum; posteriorly, the gluteus maximus, erector spinae and multifidus muscles all attach.⁵

EPIDEMIOLOGY AND CLINICAL PRESENTATION

Initial clinical findings of sacral tumors typically include localized pain, often mimicking lumbar spondylosis. Neurologic findings can occur as the tumor increases in size and include lower extremity radicular pain, perineal pain and numbness and bowel/bladder dysfunction. These neurologic symptoms can sometimes be exacerbated with a Valsalva maneuver. Reflex exam can reveal diminished Achilles reflexes due to S1 involvement or absent bulbocavernosus and anal wink reflexes. Rectal exam can sometimes reveal a palpable mass in the presacral space, and bowel obstipation from rectal compression is another frequent presenting symptom of sacral tumors.^{6,7}

The differential diagnosis for sacral tumors is summarized in Table 118.1. Metastatic lesions are the most

Table 118.1: Differential diagnosis of sacral tumors.

<i>Benign</i>	<i>Malignant</i>
Giant cell tumor	Metastasis
Osteoid osteoma	Chordoma
Osteoblastoma	Ewing sarcoma
Aneurysmal bone cyst	Osteosarcoma
Schwannoma	Chondrosarcoma
Neurofibroma	Multiple myeloma
Myxopapillary ependymoma	Lymphoma
Osteomyelitis	Invasive colorectal tumor

common sacral tumors, accounting for slightly more than 50% of all sacral neoplasms. An estimated 18% of all sacral lesions are primary malignant tumors, and 29% are primary benign lesions; however, these percentages can vary between series.⁸ Primary sacral tumors account for 1–7% of primary spinal neoplasms.⁹ Chordomas are the most common primary sacral neoplasm, representing 36–44% of all primary sacral neoplasms and 50% of malignant primary sacral tumors.^{8–11} While varying in frequency in the literature, chondrosarcoma, osteosarcoma and Ewing’s sarcoma all occur with some frequency in the sacrum; sometimes the sacrum is the site of origin, and in other cases the tumor extends into the sacrum after originating in the posterior ilium.^{9,12}

Giant cell tumors (GCTs) are the second most common primary sacral tumor after chordomas, and the most common benign sacral lesion; they represent approximately 2–13% of all primary sacral tumors and 71% of benign sacral tumors.^{7,9–11} Osteoid osteomas account for 9% of benign sacral tumors, and typically present with night pain relieved with anti-inflammatory medications. While they are rare bone tumors, more than 20% of osteoblastomas are found in the sacrum.¹² Sacral aneurysmal bone cysts (ABCs) are relatively rare, accounting for 1–2% of sacral tumors and between 2% and 13% of spinal ABCs.^{9,12–14}

Diagnosis

Imaging

Plain pelvic radiographs are often inconclusive studies of the sacrum due to overlying soft tissue and bowel gas, frequently leading to delayed diagnosis of sacral tumors.¹⁵

Blurring or obliteration of the sacral foramina is frequently caused by tumor growth. In a normal sacrum, foraminal struts should be distinctly seen, and the posterior iliac wing should be visualized as superimposed behind the sacral ala. Additionally, both the anterior and posterior margins of the sacroiliac joint should be identifiable, as this joint is oblique. If these structures cannot be delineated, then suspicion of possible sacral mass should be heightened.¹

Both computed tomography (CT) and contrast magnetic resonance imaging (MRI) scans are thus crucial to diagnosing and planning resections of sacral tumors.^{9,12,16} Chordomas are nearly always midline tumors, while GCTs are frequently eccentric.¹⁷ Both can erode into intervertebral disc spaces and the sacroiliac joints.^{12,17} Osteoblastomas typically arise in the posterior elements, often as lytic, expansile lesions surrounded by a sclerotic rim. Osteoid osteomas appear as sclerotic lesions with a nidus on CT and without soft tissue extension. ABCs typically display fluid-fluid levels on MRI; while these tumors typically arise in the posterior elements of the sacrum, most rapidly expand anteriorly into the vertebral bodies as well. Nerve sheath tumors (schwannomas and neurofibromas) can display a “target sign” on T2 MRI, in which a high-signal mass surrounds a low-signal center. As these tumors expand out of the sacral foramina, the foraminal borders are often obliterated on radiographs and the tumors assume a dumbbell shape on advanced imaging.^{1,9,17}

When a sacral lesion thought to be a neoplasm is identified, obtaining a radionuclide bone scan is useful to rule out polyostotic disease. Polyostotic findings limit the differential diagnosis, placing metastasis as most likely, with multiple myeloma, Paget disease, and vascular tumors as other possibilities.¹ To evaluate for visceral involvement or to track disease progress, positron emission tomography (PET) is another useful imaging modality.

Biopsy

Biopsies should be planned with direct consultation from the surgical team that will be performing any potential sacral resection. Biopsies can be done either open or with CT-guided core needle biopsy; the reported accuracy rate for pathologic diagnosis from sacral core needle biopsies is 92–100%.^{2,15} Biopsy sites should be placed so that the tract can be later excised with the surgical specimen, given that many sacral tumors are chordomas, which are known to readily seed adjacent tissues.^{15,18} Transrectal biopsies of sacral masses should be avoided.

STAGING

The Musculoskeletal Tumor Society (MSTS) staging system, originally developed by Enneking, separates benign and malignant tumors (Table 118.2). Benign lesions are staged with Arabic numerals (1, 2 and 3). Malignant lesions are staged with Roman numerals (I, II, III) and subdivided as A or B for intracompartmental or extracompartmental extent, respectively.¹⁹

The Weinstein-Boriani-Biagini (WBB) system was created specifically for spinal tumors. WBB staging communicates information regarding the extent and anatomic position of the subependymal giant cell tumors (SGCT) within the spinal column and is very useful in planning resection approaches (Table 118.2). The axial cross-section of the involved vertebra(e) is divided into 12 “pie slices” in a clock-face pattern; staging a tumor requires naming the slices which contain the lesion. In addition, the tumor is staged based on five concentric rings, designated A (extraosseous) to E (dural involvement).²⁰ Similarly, the Tomita system stages metastatic spinal tumors into seven categories based on location and extent of involvement (Table 118.2). Types 1–3 describe a location within the vertebral body, types 4–6 indicate extraosseous extension, and type 7 denotes multivertebral involvement.²¹

SURGICAL PLANNING

Surgical approach is dictated by tumor size and involved structures. Obtaining clean margins has been shown to be the single most important factor for minimizing the risk of recurrence, both for primary malignant and aggressive benign sacral lesions.^{2,22,23} Tumors without visceral extension can often be resected from a posterior-only approach, particularly if they are distal to S2.^{8,10,24} While many sacral tumors expand anteriorly, violation of the presacral fascia and direct involvement of the rectum does not occur.^{7,25} However, involvement of a colorectal surgical team is sometimes required during anterior dissections; the rectum can become adhered to the presacral fascia overlying the tumor, particularly if the area has received previous radiation. Primary colorectal tumors involving the sacrum also require a combined anterior/posterior approach.²⁴

Posteriorly, tumor infiltration into the gluteal and piriformis musculature does occur.⁷ After sacral resection, there is frequently a large void that may require reconstruction with biologic mesh and/or flap coverage to avoid posterior hernias.² Plastic surgeons should be included in preoperative planning, if a flap may be necessary.

Table 118.2: Summary of spine tumor staging systems.

Musculoskeletal Tumor Society (MSTS)/Enneking System

Benign

1	Well-demarcated lesion, contained within bone
2	Expansile lesion, cortical thinning
3	Soft-tissue extension, cortical breakthrough

Malignant

IA	Low-grade, intracompartmental
IB	Low-grade, extracompartmental
IIA	High-grade, intracompartmental
IIB	High-grade, extracompartmental
IIIA	Any grade, intracompartmental, metastasis
IIIB	Any grade, extracompartmental, metastasis

Weinstein-Boriani-Biagini (WBB) System

Tumor location noted as number (1-12) based on a clock face with spinous process positioned at 12 o'clock

Radial Layers

A	Extraosseous soft tissues
B	Superficial intraosseous
C	Deep intraosseous
D	Extradural
E	Intradural

Tomita System

Type

Intracompartmental	1	Vertebral body
	2	Pedicle
	3	Body and lamina
Extracompartmental	4	Epidural extension
	5	Paravertebral extension
	6	2–3 vertebrae
Multiple	7	>3 vertebrae

Neurologic sequelae of sacral resections can be debilitating and must be thoroughly discussed with patients prior to surgery. Bilateral L5 root preservation is necessary for ambulation, although a foot-drop orthosis is typically needed. Three in four patients with bilateral S1 root preservation after sacrectomy can ambulate more than 150 feet.^{10,26} Retaining both S2 nerve roots and sacrificing all distal roots can result in partial, but not normal, bowel/

bladder continence.^{2,25,26} A hemisacrectomy that leaves all roots intact on the contralateral side permits near-normal micturition and defecation.³ Patients with intact bilateral S3 roots retain bowel/bladder continence in 75–100% of cases, and approximately 50–70% of patients with unilateral S3 preservation are fully continent.^{10,23,26,27} Guo et al. identified bowel incontinence as a predictor of increased length of hospital stay ($P = 0.02$) and a cause of increased time to wound healing ($P = 0.03$).¹⁰ Impact of sacrectomy on sexual function is less well-described, but male patients who retain at least one S3 root are reportedly able to ejaculate while those with bilateral S3 root resection can achieve erection but have abnormal ejaculation. Hemisacrectomy does not substantially affect male sexual function. Females with S3-S5 bilateral root resections have reported normal sexual function, although this was determined from only two patients.^{3,26,28}

Sacral tumors often are hypervascular, with significant lumbosacral collateral circulation. Preoperative angiography should be done prior to sacral tumor resection, and embolization performed, if a tumor demonstrates significant vascularity.²⁹ Both internal iliac arteries, the median sacral artery, and other tumor-supplying arteries can be embolized, although embolizing both internal iliac arteries may predispose to a higher rate of posterior wound breakdown due to poor skin perfusion.^{2,30} Embolization using gelfoam or polyvinyl alcohol is temporary, and surgery should be performed within 24–48 hours after the embolization procedure to minimize recanalization.²⁹

Treatment

Chordomas

Chordomas are malignant tumors that originate from notochord remnants, accounting for 1–4% of malignant bone tumors. Half of all chordomas have been reported to occur in the sacrum; another 35% occur in the skull base (typically the clivus), and 15% are found in the mobile spine, although these percentages vary in different series.^{7,31–35} These tumors typically appear between ages 30 and 70, and the mean symptom duration prior to diagnosis has been reported as 2 years.^{7,33,36} Radiographically, a soft tissue mass can only be seen on radiographs in approximately 60% of cases, leading to delayed diagnosis in many cases (Figs. 118.1A to D). Calcifications within the tumor can be seen on radiographs in about half of chordoma cases, and on CT in almost 90% of cases.³⁷ Chordomas often invade

intervertebral disc spaces as well as the sacroiliac joint.¹² Histology reveals pathognomonic “soap bubble” physaliferous cells.³⁸ Dedifferentiated chordoma, a very rare form with histopathologic features of both chordoma and sarcoma, portends a more aggressive tumor with poorer prognosis.³⁹ Brachyury, a transcription factor which plays a central role in embryologic notochordogenesis, has been shown to be a reliable biomarker for chordoma. Identification of brachyury expression is often useful to histologically differentiate chordoma from mimics such as chondroid tumors and germ cell tumors.^{40,41}

Chordoma series have demonstrated a median survival after resection of 7.0–7.4 years, but with a wide range; some patients are alive more than 30 years after diagnosis.^{31,42} Five-year survival ranges from 45% to 86%, and 10-year survival varies from 28% to 60%.^{23,37,42–44} Longer survival has been significantly associated with obtaining wide surgical margins ($P = 0.0001$) and with younger patient age ($P = 0.04$).⁴³ Bergh et al. identified local recurrence as associated with a 21-fold increase in the risk of tumor-related death.³⁶

Local recurrence rates after resection also vary widely in the literature, ranging from 19% to 80%; approximately 19–30% of patients develop metastases, typically to the lungs.^{25,31,32,34,37,42,43,45–47} The mean time to metastasis has been reported as 4.2 years.⁴⁶ Intralesional resections have been reported to have double the recurrence rate than wide resections (64% vs 28%) and are a significant predictor of local recurrence ($P = 0.01$).^{42,45} The median disease-free interval after wide resection has been cited as 2.3 years, compared to just 8 months after subtotal resection ($P < 0.0001$). In subtotal resections, adjuvant radiation therapy (RT) improved the disease-free interval from 8 months to 2.1 years ($P < 0.02$).³¹ Chordoma extension into the sacroiliac joint, gluteus maximus and piriformis muscles has been shown to predict higher recurrence rates, and thus wider margins of these structures should be taken in these cases.⁴⁸ Postresection MRI should be done for surveillance every 3 months in the first year, every 6 months in the second year, and then annually.³⁸

Chordomas are relatively radioresistant, so RT is generally employed only in cases of contaminated margins or recurrences.⁴³ However, hadron RT (protons or carbon ions) has shown promise for obtaining improved results in chordoma control.^{49–55} Proton RT has demonstrated an added benefit of having minimal to no deleterious effect on patient quality of life during treatment.⁵⁶ These technologies are only available in a handful of tertiary centers,

Figs. 118.1A to D: Images from a 68-year-old male with a sacral chordoma, who presented with 3 months of low back pain, perianal numbness, and urinary incontinence. (A) A pelvic radiograph showed a large area of opacity overlying the sacrum with obliteration of the sacral foramina. (B) Axial CT demonstrated a large mass involving the sacrum with internal calcifications. (C) T2 MRI revealed that the tumor abutted S2; note that the rectum is being compressed but that the tumor has not violated the presacral fascia. (D) Axial T2 MRI demonstrated the posterior extent of the tumor, with infiltration into the gluteus maximus on the left; Surgical resection required a staged anterior/posterior surgery and achieved negative margins, with sacrifice of both S2 nerve roots. One year after his sacrectomy, he developed local recurrences in his ilium, and distant metastases to his lungs; he was started on palliative imatinib chemotherapy.

and larger clinical studies are still needed to determine how best to use these modalities to treat sacral chordomas. Hamamoto et al. effectively treated a recurrent sacral chordoma with palliative RFA when surgery, RT and embolization had failed to control the tumor.⁵⁷ Similarly, Kurup, et al. employed cryotherapy to treat five sacral/ischiorectal chordomas that had recurred after previous surgical resection.⁵⁸

Historically, chemotherapy has been largely ineffective against chordomas. However, new research has found that most chordomas over-express platelet-derived growth

factor receptor- β (PDGFR- β).⁵⁹ Imatinib is chemotherapy drug that specifically targets PDGFR- β , and has shown promising results against chordoma in initial trials.^{60,61}

Giant Cell Tumors

Sacral GCTs are benign but often aggressive tumors that can cause substantial bone erosion and neurologic impairment; however, GCTs can metastasize in 1–14% of cases, typically to the lungs.^{62–64} GCTs nearly always occur after skeletal maturity, in contrast to ABCs, which can have similar radiographic features to GCTs but typically occur

in skeletally immature patients.¹ Definitive treatment guidelines for sacral GCTs have not been established. In a literature review of 166 sacral GCT cases, Leggon et al. concluded that sacral GCTs had an overall recurrence rate of 48%, but that no patients who underwent wide excisions experienced recurrence.⁶⁵ Guo et al. treated 24 sacral GCT patients more conservatively, with intralesional curettage or partial excision. They reported an overall recurrence rate was 29%, with 70% of patients recurrence-free at 5 years. Mean time to recurrence was 13 months.²⁷ Boriani et al. provided evidence that en bloc resection of all MSTS/Enneking stage 3 spinal GCTs and intralesional resection of stage 2 spinal GCTs produces acceptable recurrence risk.⁶⁶

Li et al. reported the treatment of 32 sacral GCT patients. All patients underwent preoperative embolization. Patients then underwent wide resection ($n = 2$), marginal resection ($n = 11$), marginal resection plus curettage ($n = 12$), or curettage alone ($n = 7$). Curettage was supplemented with adjuvant ethanol application or argon beam coagulation. Twelve patients (37.5%) developed local recurrence, with the marginal resection group having a significantly lower recurrence risk than the curettage group (18% vs 71%, respectively; $P = 0.05$). These authors concluded that curettage alone should not be used to treat sacral GCTs, instead proposing a treatment algorithm based on GCT location within the sacrum. They argued that S3-S5 tumors should undergo en bloc resection, mid-line tumors should undergo proximal curettage (S1-S2 segments) and distal marginal resection (S3-S5 segments), and eccentric proximal tumors should undergo marginal resection with preservation of all contralateral nerve roots.⁶⁷ Intralesional resection of sacral GCTs can be augmented with cryoablation or argon beam coagulation.⁶⁸⁻⁷¹

In addition to surgical treatment, bisphosphonates and denosumab have shown effectiveness against GCTs as adjunct therapy when combined with surgery, or as stand-alone medical treatment for unresectable GCTs.^{23,67,72-75} Use of these medications both preoperatively and postoperatively should be considered. Also, serial arterial embolization has shown ability to control growth of sacral GCTs, improving pain and neurologic symptoms. Embolization should be considered as solo therapy in cases of unresectable or recurrent sacral GCTs, and is repeated at intervals of 4-6 weeks until symptoms improve and there are radiographic indications of decreased vascularity with reossification.^{9,29,76,77}

Radiotherapy has also been successfully utilized for unresectable sacral GCTs; however, the benefit must be

weighed against risk of sarcomatous conversion associated with the use of radiotherapy against GCTs.⁷⁸

Metastatic Disease

Sacral metastases are increasing in frequency due to longer survival in patients with advanced cancer. Primary management for metastatic bone disease is systemic treatment with chemotherapy for the primary tumor along with radiation for local control. Radiotherapy has been utilized for many years to treat metastatic bone disease and is considered frontline treatment with the primary benefit being pain relief.^{79,80} Another option for local control is open surgical treatment, which is typically invasive and morbid. Indications for surgery are pain palliation (typically after failure of other treatments), neurologic impingement, and instability.^{81,82} Several studies have demonstrated clear benefit of surgical decompression with or without radiation over radiation alone to maintain ambulation in patients with metastatic spinal cord compression.^{83,84} Feiz-Erfan et al. reported on 25 patients with sacral metastases who underwent surgical treatment. Despite a 40% complication rate, overall these patients did experience substantial pain relief.⁸⁵ Quraishi et al. found that 30% of patients undergoing urgent cauda equina decompression caused by a lumbosacral metastasis experienced at least one Frankel grade of neurologic improvement after surgery.⁸⁶

Newer techniques have expanded the treatment options for sacral metastases. Embolization of spinal metastases has demonstrated effectiveness in some studies when used as a solo treatment; most reported cases involve renal cell carcinoma (RCC). Kuether et al. embolized thoracic and sacral metastases in a single RCC patient who experienced neurologic improvement and tumor stabilization lasting at least 5 months.⁸⁷ O'Reilly et al. embolized spinal RCC metastases in 4 patients, noting improved neurologic function lasting for 12 weeks.⁸⁸

Percutaneous sacroplasty using polymethylmethacrylate (PMMA) cement has been shown in numerous series to reduce pain and improve ambulation in patients with tumor-related sacral insufficiency fractures.⁸⁹⁻⁹⁶ Nebreda et al. performed sacroplasty as well as cementation of the sacroiliac joint in a patient with a large S1-S2 metastatic lesion extending into sacroiliac joint who was experiencing intractable pain with weight-bearing.⁹⁷ One potential complication of sacroplasty is cement extravasation; tumor patients are at higher risk of this than patients with osteoporotic fractures because of the extensive cortical destruction often caused by lytic tumors.^{90,98} Cement extravasation

can catastrophically embolize to the pulmonary circulation or cause neurologic impairment.^{99,100} Moussazadeh et al. noted PMMA extravasation in more than 70% of sacroplasty patients, although none experienced any neurologic impairment.⁸⁹ Pereira et al. reported that 4 of 58 sacroplasty patients (7%) experienced neurologic deficits from cement leakage; two patients improved with observation, but two required surgical decompression.⁹⁰ CT-guided sacroplasty is preferable over fluoroscopy alone; CT better demonstrates cement leaks during injection and better visualizes sacral anatomy. Lateral fluoroscopic sacral views are complicated by the superimposed iliac wings.^{94,98,101}

Radiofrequency ablation (RFA) and cryoablation are two other percutaneous techniques for treating osseous sacral metastases. Use of RFA for bone metastases was first reported by Dupuy et al.¹⁰² and multiple series have demonstrated its effectiveness in the sacrum and mobile spine with minimal complications.¹⁰³⁻¹⁰⁶ Eighty percent of patients experience pain relief after the procedure, and patients frequently report pain improvement and activity increase up to 18–20 weeks post-procedure.¹⁰³ Nakatsuka et al. reported that 4 of 17 (24%) of patients treated with RFA for spinal metastases experienced neurologic damage, and that in all cases the tumor had disrupted the posterior vertebral body wall.¹⁰⁷ However, other studies have not described a complication rate this high. RFA can be combined with cement osteoplasty to stabilize lytic lesions after ablation, with good pain relief within 24 hours.¹⁰⁷⁻¹⁰⁹ Cryoablation can be utilized for osteoblastic or sclerotic lesions, as the increased bone density does not create impedance as with RFA. Use of CO₂ epidurography to create an insulating layer, as well as placement of a thermocouple to monitor the temperature surrounding the neural tissue, should be used to prevent inadvertent neurologic injury.¹¹⁰ Neuromonitoring is often utilized as well. As with sacroplasty, CT guidance should be used for these procedures. Lee et al. utilized a multimodal approach to a patient with a sacral RCC metastasis causing severe pain and lower extremity paresthesias. They first embolized and then cryoablated the tumor. Finally, they performed PMMA sacroplasty, and the patient's pain and neurologic impairment substantially improved within a week.¹¹¹

Aneurysmal Bone Cysts

In contrast to GCTs, ABCs are generally thought to not have metastatic potential. However, ABCs are often locally aggressive, causing substantial osseous destruction, pain

and neurologic impingement (Figs. 118.2A to D). As with GCTs, serial arterial embolization can be employed to treat ABCs nonsurgically.^{9,112,113} Boriani et al. retrospectively reviewed 71 spinal ABCs, 9 (13%) of which were sacral. Enneking stage 1 and 2 lesions were effectively treated with intralesional resection or serial embolization, while stage 3 lesions required en bloc resection to prevent recurrence.¹¹⁴ Similar to GCTs, denosumab has demonstrated promise for controlling and even shrinking spinal ABCs in small series, particularly in cases when embolization could not be performed because of vascular anatomy.¹¹⁵

Nerve Sheath Tumors

Schwannomas and neurofibromas are both rare in the sacrum, although of the two schwannomas are much more common. Often these tumors present with neuropathic pain but without neurologic dysfunction, although they can also cause bowel/bladder dysfunction. While en bloc resection is the preferred treatment, nerve sheath tumors may have an intradural component and thus require intralesional resection. If the tumors involve the S1 or S2 roots, intraoperative nerve stimulation and electromyography (EMG) are essential during resection to minimize damage to nerve fibers.^{15,116} Several cases have also been reported in which stereotactic body radiation therapy (SBRT) has been utilized to treat sacral schwannomas effectively and without neurologic injury.^{117,118}

Ewing's Sarcoma and Lymphoma

Ewing's sarcoma and primary bone lymphoma can arise in the sacrum, albeit rarely. Histologic appearance of these tumors can be similar, as both are characterized by small, round blue cells. Ewing's sarcoma has a characteristic t(11;22) chromosomal translocation, and is rare in patients older than 30 years of age.¹¹⁹ In a series of nearly 800 Ewing's patients, Bacci et al. found that only 2% of cases involved the sacrum. Importantly, they noted that sacral Ewing's tumors had a poorer prognosis compared to tumors elsewhere in the spine and in the extremities.¹²⁰ Treatment typically consists of neoadjuvant chemotherapy followed by surgery; adjuvant radiation may also be used.

Primary lymphoma of bone typically occurs in patients older than 40 years of age, with 10% of cases arising in the spine; a small subset of these is sacral tumors. Typically these tumors are very sensitive to chemotherapy and radiation, and surgery is rarely needed.^{119,121,122}

Figs. 118.2A to D: Images from a 19-year-old female with a sacral aneurysmal bone cyst, who presented with two years of sacral pain, exacerbated by 2 months of posterior leg radicular pain and bowel obstipation. (A) A large lytic area was eccentrically located within the sacrum on the pelvic radiograph. (B) Axial T2 MRI. (C) CT demonstrated a large mass eroding the sacrum and extending into the pre-sacral space. The tumor was removed via an all-posterior approach, sacrificing the S5 nerve roots only. Most of the tumor was removed en bloc; there was a positive margin superiorly that was curetted and treated with adjuvant alcohol and phenol. (D) At 5-year follow-up, the patient remained disease-free. Gross pathology sectioning of the tumor demonstrated a bony cystic lesion, characteristic of ABC.

Use of Stereotactic Radiation

Advances in radiation delivery technology have expanded options for using RT against sacral tumors. Conventional external beam radiation generally lacks the targeting accuracy necessary to avoid significant damage to the sacro-pelvic neurovascular structures while regularly delivering therapeutic doses.^{117,118} However, the advent of stereotactic body radiation therapy (SBRT) has made radiation a much more useful treatment for spinal tumors. Because the radiation dose can be very specifically conformed during delivery, malignant lesions can now often be treated with a single

dose of radiation while protecting the spinal cord from damage.^{118,123} Candidates for SBRT typically have either new focal or oligometastatic lesions and stable systemic disease, or have recurrent lesions after RT and are poor surgical candidates. Patients with neurologic compromise or less than 5 mm distance between the tumor and spinal cord are not candidates for SBRT.¹²⁴ Benign sacral tumors such as GCTs and ABCs can also be radiated using SBRT if surgical resection would cause unacceptable morbidity. However, although SBRT minimizes radiation damage to surrounding tissues, the risk of radiation-induced sarcoma still exists. Because of the increasing evidence for other

treatments such as serial embolization and denosumab, SBRT for benign tumors should still be used as a relative last resort, particularly in younger patients.^{114,117}

RESECTION TECHNIQUES

Appropriate perioperative planning is critical for achieving a successful surgical procedure. Massive blood loss can occur during sacrectomies, with bleeding up to 80 L reported for two-stage total sacrectomies.^{9,125} Intralesional resections of sacral tumors can also result in operative blood loss in excess of 30 L, even after preoperative embolization.² The anesthesia team should be prepared to administer large volumes of transfused blood throughout the case, replenishing platelets and coagulation factors in accordance with a massive transfusion protocol.

Neuromonitoring may or may not be useful, depending on the level and objective of the planned surgery. If en bloc resection is planned, then whichever roots are involved with the tumor must be sacrificed. However, if a nerve-sparing approach is performed, such as a debulking of a metastatic tumor, then neuromonitoring of the anal sphincter may be informative, particularly if the tumor is at or above S2. If posterior instrumentation is being placed, then triggered EMG should be performed for each pedicle screw to insure safe placement. Monitoring somatosensory evoked potentials (SSEPs) of the upper and lower extremities provides useful information if the case is lengthy, alerting the surgical team to compressive neuropathies from patient positioning.

Anterior sacral approaches are done to directly ligate vessels feeding the tumor, and to separate presacral visceral structures from the tumor to identify the appropriate anterior level for the sacral osteotomy. A longitudinal midline abdominal incision is used, and either a transperitoneal or retroperitoneal approach is made to the anterior sacrum. The iliac vessels, ureters, and femoral and obturator nerves should be identified and freed. If a rectus abdominus myocutaneous flap is to be used in reconstruction, the flap can be prepared during the anterior approach to allow pull-through once the posterior resection is completed. A silastic sheet can be placed between the sacrum and rectum to maintain demarcation and assist with the posterior resection.^{9,126,127}

The posterior approach is made using an inverted-Y incision ("Mercedes logo" incision) centered over the sacrum, with the arms of the Y extending around the anus and over the buttocks. Prior to skin sterilization and draping, the rectum should be packed with gauze to allow easy

palpation of the rectum during resection, minimizing the risk of inadvertent perforation. The resection may require excision of a substantial portion of the gluteus maximus muscle as a wide margin, if there is posterior tumor extension. The distal extent of the tumor is identified, and the coccygeal attachments of the sacral ligaments and pelvic floor muscles are released with electrocautery. The surgeon can then bluntly dissect along the anterior distal sacrum, packing surgical sponges into the presacral space to separate the rectum from the tumor. Once the lateral border of the tumor is identified, the piriformis muscles are resected as they emerge laterally from the anterior surface of the sacrum. Care must be taken to identify and protect the sciatic nerves at this portion of the resection. The proximal extent of the tumor is then delineated and the appropriate level selected to begin the posterior-to-anterior sacral osteotomy. The sacral canal is entered by performing a laminectomy. Once the dura is identified, the sacral nerve roots can then be unroofed at the level of the osteotomy using Kerrison rongeurs. Just distal to the pair of sacral roots that are not involved in the tumor and will be preserved, the dural sac is tied off with silk sutures and ligated. Osteotomes can then be used to create a cut through the sacrum while protecting the preserved nerve roots with Penfield neural retractors.^{9,126,127}

Cho et al. achieved en bloc resection of a sacral alar chondrosarcoma using computer-aided navigation. They were able to preserve all sacral nerve roots while performing the surgery through a posterior-only approach.¹²⁸ Sternheim et al. demonstrated that use of computer navigation can produce highly accurate sacropelvic osteotomies in a simulated sacral tumor model. Navigated osteotomies were significantly more accurate than non-navigated cuts ($P < 0.01$).¹²⁹ Bederman et al. recently utilized a surgical robotics system to guide osteotomies for a sacroiliac osteosarcoma resection.¹³⁰

RECONSTRUCTION TECHNIQUES

Stable reconstruction after resection of large tumors involving the sacrum is critical and often difficult. Biomechanically, the sacrum functions as the keystone of the pelvic ring, transferring axial loads from the entire spine to the hip joints via the sacroiliac joints. Substantial mechanical loading occurs at the lumbosacral and sacroiliac articulations with ambulation, standing and sitting.¹³¹ Typically if S1 is left intact, corresponding to 50% of the sacroiliac articulation, then the sacrum and pelvis are stable and do not require reconstruction.^{2,9,132,133}

Fig. 118.3: Schematic representation of a 4-rod, 4-iliac screw technique for reconstruction after total sacrectomy.
Source: Adapted from Reference 137.

If reconstruction is needed, numerous techniques have been described. Broadly, constructs should restore posterior pelvic ring integrity, lumbopelvic continuity and anterior column support.¹³⁴ In addition, constructs should be rigid enough to enable early patient mobilization.¹³⁵ A modified Galveston rod technique was an early method of lumbopelvic reconstruction, but the iliac rods were noted to frequently loosen and break.^{9,136} In attempts to improve stability, Melcher and Harms employed dual contoured cylindrical cages to provide support between the inferior-most lumbar endplate and the posterior ilium, backed up with posterior segmental instrumentation.¹³¹ Kelly et al. and Mindea et al. performed biomechanical testing on several instrumentation configurations after cadaveric total sacrectomy, concluding that a 4-rod, 4-iliac screw construct had the most rigidity (Fig. 118.3).^{136,137} Two other studies tested a modification of this 4-rod technique by adding fibular strut grafts to form a triangle between the inferior endplate of the L5 body to the pelvis. The fibular grafts increased stiffness and achieved better load dispersion than the 4-rod construct alone by supporting the anterior column, although it should be noted that this technique requires a very extensive surgical exposure.¹³⁸⁻¹⁴⁰ Gillis et al. utilized a 2-rod construct with a unilateral vascularized fibular graft for reconstruction after a hemisacrectomy (Fig. 118.4).¹⁴¹

Fig. 118.4: Technique for reconstruction after hemisacrectomy. A vascularized fibula graft is placed between the L5 inferior endplate and the ischium, held in place by compression of the rod construct. A shorter fibular allograft is placed as a strut between the posterolateral L5 body and the posterior ilium.
Source: Adapted from Reference 141.

Based on current evidence, four iliac screws should be used for total sacrectomy reconstructions. Typically, 8.5 mm diameter screws can be placed between the inner and outer tables of the ilium. Screw length should be maximized (minimum length 80 mm) to obtain purchase in the supra-acetabular bone, placing the screw tips well anterior to the lumbosacral pivot point. Doing so improves biomechanical stability, thereby reducing the risk of screw pull-out and instrumentation failure.¹⁴²

COMPLICATIONS

The intraoperative and perioperative complication rate of sacral resections is high. Wound complications occur in 25–50% of cases, often requiring myocutaneous flap coverage. Previous radiation treatment to the surgical field is associated with increased risk of wound breakdown.^{24,42,46,132} Several studies have found that use of a rectus abdominus myocutaneous flap at the time of resection significantly reduced wound complications ($P = 0.01$).^{42,43} Sacral alar stress fractures can also develop, particularly after RT.⁴³ Cerebrospinal fluid leaks, vascular injuries, bowel perforations, and implant failures are other risks of sacral resections.^{9,82,86}

CONCLUSION

In conclusion, sacral tumors present diagnostic and therapeutic challenges for spine surgeons. An experienced multidisciplinary team is critical to achieving the best outcomes for these patients. Resections can involve substantial blood loss and carry a high risk of wound complications. Reconstruction techniques have improved as posterior segmental instrumentation options have expanded, and most patients can return to ambulation even after total sacrectomies. Sacrifice of sacral nerves carries significant implications for patient quality of life, requiring thorough preoperative patient discussion. Nonoperative treatments have expanded over the past decade, and include medical therapy with denosumab and bisphosphonates, serial embolization, sacroplasty and percutaneous ablations. In addition, stereotactic body radiation treatments have greatly improved the accuracy of RT for sacral malignancies. More high-level evidence is needed to clarify treatment algorithms and best practices for sacral tumors.

KEY POINTS

- Sacral tumors are challenging neoplasms, requiring experienced multidisciplinary teams for effective treatment
- Surgical resection with wide margins remains the mainstay treatment for most primary sacral malignant and aggressive benign tumors
- Prior to surgical treatment of sacral tumors, patients should be thoroughly counseled as to the implications of morbidity after sacral nerve root sacrifice, including bowel and bladder incontinence as well as sexual dysfunction
- Nonsurgical treatment options for sacral tumors are expanding: medical therapy with denosumab or bisphosphonates, serial embolization, sacroplasty and percutaneous ablations can all be employed against a number of sacral neoplasms
- Stereotactic body RT has made radiation a much more viable treatment option for malignant sacral tumors.

Metastatic Tumors of the Spine

Snapshot

» Clinical Findings

INTRODUCTION

Bone is a frequent site of occurrence of metastases from carcinoma, second only to lung and liver.¹ The bony elements of the spine, mostly the vertebral body, are the most frequently affected region. The vertebral bodies are reached largely via the bloodstream and neoplastic substitution of the bone tissue causes progressive structural destruction, leading to loss of stability and resultant compression of the nervous structures within the spinal canal.

There is evidence that blood from many anatomic sites drains directly into the axial skeleton. In postmortem studies, Batson² demonstrated that venous blood from the breast and the pelvis flowed not only to the vena cava but also into a venous plexus extending from the pelvis to epidural and perivertebral veins. The drainage of blood via the vertebral venous plexus may explain, at least in part, the tendency of breast, prostate, kidney, and lung to produce metastases in the axial skeleton. Currently, this is not accepted as the complete explanation, as molecular and cellular biology of the tumor cell and the tissue to which they metastasize influences the pattern of metastatic spread. Tumor dissemination is a multistep process involving specific tumor and host-tissue interactions via specific molecular determinants. In recent years, many basic and translational studies focused on angiogenesis, which enables growth of the primary tumor, access of tumor cells to the systemic circulation, and growth of micrometastatic deposits.

It is estimated that 20–30% of patients affected by carcinomas will develop symptomatic spinal metastases^{3,4} and about 40% will have evidence of bone metastases at autopsy.⁵ Back pain in a patient with a previous history of cancer should first arise the suspicion of metastatic disease rather than degenerative disease, which is the cause in the majority of the population. As stated by Perrin,⁶ “it is axiomatic that a cancer patient with new-onset back or neck pain harbors spine metastasis until proven otherwise.”

Conversely, primary bone tumors of the spine are extremely rare, with occurrence ranging from 20 to 50 times less frequently than metastasis. The knowledge of clinical and imaging patterns, as well as the epidemiology, incidence, and characteristics of different primary bone tumors, is crucial to suspect these diagnoses to perform a biopsy. Infectious bone diseases are also to be considered among the differential diagnosis. The different clinical pattern and images of disc erosion usually suggest the diagnosis, which will be confirmed by histology and cultural exams.

The incidence of vertebral metastases is increasing in time, paralleling the increasing life expectancies of cancer patient secondary to the improvement in medical, surgical, and radiotherapeutic treatments.⁷ Quality of life becomes the major concern not only for patients whose primary tumor is controlled but also for patients with widespread disease, where the pain cannot be relieved by drugs and/or ambulation is restricted by spinal insufficiency.

The choice of the most suitable treatment is of crucial importance to avoid that the patient be severely disabled by uncontrolled or recurrent spinal metastases, which is particularly difficult to accept if the primary tumor is controlled.

In order to improve the patient's quality of life, neurological function must be protected or restored, the spinal column must be stabilized and the pain must be relieved.

The reduction in the tumor mass, or debulking, or complete excision of the lesion is important⁸ for the local control of the disease. Bone metastases are evidence of a systemic disease, and therefore require multidisciplinary treatment, integrating radiotherapy,⁹ chemotherapy, and surgery.^{10,11} The best treatment protocol to adopt is still a matter of discussion.¹ The commonly accepted indications for surgery are symptomatic cord compression, spinal instability, intractable pain, and failures of precedent treatments. What is still debatable is the choice of the optimal surgical technique. New procedures and progresses in technology make the decision very difficult.

A wide range of surgical and parasurgical techniques are available, from the most aggressive (enbloc vertebrectomy, gross total excision) to minimally invasive techniques (vertebroplasty, percutaneous fixation, thoracoscopic excision). The interest in minimally invasive procedures is increasing by combining these techniques with attempts at tumor reduction via radiofrequency ablation (RFA)¹² or electrochemotherapy. What is unquestionable is the need for a multidisciplinary decision-making process to tailor the treatment for each patient, carefully considering cost-benefit ratio of all the possible treatment options available today. Staging systems and algorithms are proposed for the reproducibility of these decisions.

CLINICAL FINDINGS

Pain is the first and most serious symptom that patients with spinal tumors complain of. Pain is extremely frequent, nonspecific, and easily undervalued. Many times the pain is unrelated to activities and increases during the night. Vertebral collapse or impending fracture may change the character of the pain.

Many factors influence the onset of pain: tumor infiltration into the vertebral body expands and breaks the cortex, stretching the periosteum, stimulating the pain receptors of the periosteum; tumor invasion of the surrounding soft tissues; tumor invasion of the spinal canal and compression of the spinal cord and/or the nerve roots; and bony

erosion by the tumor can weaken the vertebra and cause mechanical pain.

In this case of loss of structural support, the patient complains of pain with standing when thoracic and lumbar vertebrae are involved or compelled to support the neck in the case of cervical location involvement. Pathological fracture results in an acute increase in pain and difficulty to stand in ways similar to that caused by a traumatic fracture. The structural alteration may lead to spinal instability and/or compression of the spinal cord. Neurological symptoms are not rare at the onset either as radicular pain and motor weakness due to root compression or as quad- or paraplegia due to cord or cauda equina compression secondary to canal encroachment.

Imaging and Diagnostic Studies

The majority of spinal metastases occur in the vertebral body, arising from the posterior wall and sometimes expanding into one of the pedicles. Not >5% are located exclusively in the posterior elements; in these cases, biopsy is mandatory to exclude other more probable conditions. A lytic pattern (Figs. 119.1A and B, 119.6A, and 119.7A and B) is more frequent than blastic (Figs. 119.2B and 119.3B). Rarely both aspects can be encountered in the same patient (Figs. 119.3A and B). A mixed aspect combining radiolucent and radiopaque lesions is most commonly found (Fig. 119.3C).

Osteolysis resulting in bone destruction does not appear to be simply a mechanism of tumor-replacing bone, but rather activation of osteoclasts causing dysregulated remodeling of bone.¹³ Osteoblastic metastases, mostly as a result of prostate cancer (Fig. 119.2B), though sometimes observed in breast metastases (Figs. 119.3A and B), arise via the stimulation of osteoblasts by several factors, including transforming growth factor beta, fibroblast growth factors, prostate-specific antigen (PSA), and bone morphogenetic protein. Mixed aspects are combinations of neoplastic-induced erosive actions and bone-forming reaction or collapse of trabeculae. Sclerotic reaction around the lesion or ossification inside the tumor mass can be a sign of good response to therapy (Fig. 119.7E).

The presumed cascade of events of lytic metastases is correlated to the resolution and the specificity of different imaging techniques. Magnetic resonance imaging (MRI) can demonstrate the bone marrow invasion, the first step of metastatic seeding inside the cancellous bone of a vertebral body, even before any destructive effect on bone.

Figs. 119.1A and B: A 69-year-old male. T12 lytic lesion. Metastasis from lung cancer. Pain related to standing position and during bending. No body collapse and unilateral involvement of posterior elements. SINS 9

Figs. 119.2A to C: A 77-year-old male. Prostate carcinoma. Nocturnal back pain. (A) PET scan positive in T12. (B) Sclerotic metastasis SINS score 4. (C) Bone Scintigraphy shows uptake of the contrast at T12.

Uptake of the tracer in bone scintigraphy becomes evident as soon as osteoblast activity initiates (Fig. 119.2C), while computed tomography (CT) scans begin showing changes when trabecular destruction appears. Finally, plain films show diagnostic images when the tumor provokes cortical erosion, destroys >30% of cancellous bone or causes a significant sclerotic reactive bone formation (Fig. 119.6F). Because of anatomical superimposition of the sternum and ribs, lesions occurring from C6 to T4 are particularly difficult to visualize on plain films; CT scan and MRI become mandatory to detect a lesion suspected on bone scintigraphy. The well-known “winking owl” (Fig. 119.5) finding signifies the disappearance of the pedicle in the coronal

view provoked by a lytic metastasis eccentrically destroying the vertebral body and the pedicle is a late manifestation of the disease. With improved diagnostic ability and improved awareness, the diagnosis of metastatic spinal lesions should be made quite earlier.

The role of conventional plain radiograph is limited to follow-up of hardware (Fig. 119.3C) or to the analysis of sagittal balance when performed in standing position (Fig. 119.4D).

Computed tomography scans allow detection of both lytic and blastic lesions: blastic lesions easily identified as increased calcification and lytic lesions visible as fat is replaced by tumor in the bone marrow. Erosion of the

Figs. 119.3A to C: A 64-year-old female. Multiple metastases from breast cancer (A and B). Metastatic cord compression at T7-T8. Sclerotic lesion in T8 without fracture, with unilateral involvement of posterior elements; SINS 3. Lytic lesion in T7 in absence of pathological fracture with unilateral involvement of posterior elements. Normal alignment; SINS 5. (C) Due to spinal cord compression the patient underwent to a surgical decompression and stabilization.

Figs. 119.4A to D: A 63-year-old female T1-T2-T3-T4 metastases from breast cancer. Cervical-dorsal pain under loading, needs to support the head with the hands. (A) MRI T2 weighted sagittal image of the cervicothoracic spine showing collapse, subluxation and translation. Collapse of T2 vertebral body. (B) Axial image of T2 showing bilateral involvement of the posterolateral complexes. Other metastatic localization at T4; SINS 18. (C and D) Postoperative X-ray; C3 to T8 decompression and stabilization.

cortex and soft tissue encroachment can also be seen, enhanced with the administration of intravenous contrast media.

Magnetic resonance imaging allows early detection of changes in bone marrow consistency and is considered the best procedure in soft tissue investigation. On T1-weighted images, normal bone marrow is hypointense in children, and then progresses with age from isointense to hyperintense in elderly people. The signal for metastatic

deposit is of low intensity, very low for osteoblastic lesions (Fig. 119.4A). On T2-weighted images, the signal is variable, mostly hyperintense. The stir T2 sequence is more sensitive than T1- and T2-weighted images for detecting metastases, but conversely is less sensitive for observing extravertebral involvement (Figs. 119.4B to D).¹⁴ These sequences are also hyperintense in osteoporotic fractures (Fig. 119.8); however, cancellous bone pattern disruption, cortical erosion, and soft tissue masses will be helpful to differentiate metastatic lesions.

Fig. 119.5: Winking owl sign.

Figs. 119.6A to F: A 58-year-old male. Solitary metastases from hypernefroma. Pathologic fracture of L2 (A and F) with osteolysis involving >50% of the vertebral; non involvement of posterior elements. SINS score: 12. (B and C) En bloc resection with wide margins, upper view. (D) Postoperative X-ray showing anterior reconstruction with carbon fiber stackable cage and posterior stabilization with screws and rods. (E) Axial CT scan image showing the carbon fiber cage, in the right position, filled with autologous bone graft.

Bone scintigraphy with technetium-99 is a screening technique with high sensitivity but low specificity in detecting lesions (Fig. 119.2C). It evidentiates the bone-forming reaction but does not demonstrate the presence of tumor tissue itself unless pathologic bone is formed. It reflects the rate of bone turnover, so “hot spots” can be seen

in many benign lesions, like osteoid osteoma, trauma, and infections. It is a relatively low-resolution technique and may miss small lesions or lesions that are purely lytic. The advantages are that it is a whole body screening method, low cost, and low irradiation of the patient. It is rarely used alone; it needs to be considered in association with other

Figs. 119.7A to E: A 76-year-old male. Hepatocellular carcinoma. Metastases in T11 with collapse of the endplates (A and B). Severe pain, preventing to standing, <50% body collapse, no involvement of the posterolateral complexes, normal alignment. SINS score: 12. (C and D) Radiofrequency ablation and minimally invasive fixation. (E) 18 months follow-up, no signs of local recurrence, bone reconstruction.

Figs. 119.8A and B: A 77-year-old female. 3 weeks before sudden back pain, not related to trauma, after mild effort. (A and B) T2-weighted and STIR sequence shows hyperintense image in L4 without pattern of disruption neither soft tissue masses. Suggestive for osteoporotic fracture.

imaging technique, such as CT or MRI to better characterize any abnormalities.

Positron emission tomography (PET) previously considered as a research tool is now rapidly increasing in clinical applications specifically in detecting and staging metastatic tumors (Fig. 119.2A). Unlike conventional anatomic imaging methods, PET is able to detect functional and metabolic changes and is intrinsically more sensitive. The most commonly used tracer in clinical PET is 18 F-fluoro-deoxyglucose (18FDG); FDG-PET has higher costs but a far better spatial resolution than ^{99m}Tc bone scan. Its major advantage is imaging tumor specifically and not bone formation. It is a whole body method for detecting bone and soft tissue tumors based on the increased glucose avidity of tumors with increased metabolism. The disadvantage is that not all bone tumors are hypermetabolic and therefore not constantly detectable. Kidney, prostate, and ovarian carcinoma as well as breast carcinoma at early stages are poorly glucose avid; mucin (gastrointestinal) tumors are doubtful; while lung cancer, lymphoma, and advanced breast tumors are very avid with the highest possibility of detection. For these and other conditions under evaluation, FDG-PET seems to be a promising tool for staging and for evaluating the response to therapy.

For both diagnostic and therapeutic assessment of infective spondylodiscitis, FDG PET/CT has already been proven to be sensitive and accurate.¹⁵ Standardized uptake value (SUV) at diagnosis of spondylodiscitis was $8.6 (\pm 3.7)$ in 34 patients.¹⁶ The quantitative analysis of SUV is therefore helpful to differentiate from bone tumors that have a max SUV of $4.3 (\pm 3.1)$.¹⁷

As reported previously, max SUV is variable in metastases, mostly inferior to the value detected in infectious disease. In cases of non-small cell lung cancers, the SUV are higher and the prognostic value of preoperative 18F-FDG PET has been recently enhanced.¹⁸

Tumor Markers

Several markers are elevated in metastatic breast cancer and can confirm the radiological suspect. These include serum carcinoembryonic antigen, the mucin markers CA 15-3 and CA 549, and tissue plasminogen activator. An elevated level of CA15-3 is highly suggestive of metastatic disease, but 30–40% of patients with bone metastasis from breast carcinoma have normal CA 15-3 levels.¹⁹ Prostate-specific antigen has proven useful in the early diagnosis, staging, and follow-up of patients with prostate cancer;

however, poorly differentiated tumors produce lower levels of PSA.

Diagnosis

Detecting a lytic or blastic symptomatic radiographic finding is not pathognomonic for metastatic disease even in a patient with known cancer. Moreover, patients with two or more cancers are not rare, and imaging is not helpful to suggest which is the symptomatic metastasis. The differential diagnosis of spinal lesions should also include infectious diseases, primary malignant, and benign tumors. For example, hemangiomas are encountered frequently. Osteoporotic collapse or compression fractures (Figs. 119.8A and B) are very frequent in the elderly and in metabolic diseases, but can occur during the clinical course of a tumor patient, particularly if submitted to chemotherapy and if physical activity is reduced.

A spine metastasis can be the first clinical occurrence and can remain for a long time the only manifestation of the distant spread of an unknown disease; familiarity with the radiographic pattern of different primary bone tumors is helpful to guide diagnosis. As stated above, lesions arising from the posterior arch should be suspected for primary tumor:

- *Chondrosarcoma*: Lytic, with round ossifications, sometimes evident is the original exostosis.
- *Aneurysmal bone cyst*: Bubbly with typical double density content on MRI or contrast-enhanced CT scan; a circumferential sclerotic border with erosion of the normal bone.
- *Osteblastoma*: Mixed, mostly blastic, sometimes with fuzzy borders.
- *Hemangioma*: Corduroy image in coronal and sagittal, corresponding to polka dot images on transverse sections is suggestive for hemangioma. Hemangiomas are the most frequent benign bone condition in the spine, occasionally found more lytic and locally aggressive.
- *Hemangioendothelioma*: Characterized by lytic change of the vertebral profile, mostly enlarged with possible peripheral ossified border, and internal trabeculae of different thickness. Hemangioendothelioma is an infrequent lytic tumor of vascular origin.
- *Chordoma*: A lytic lesion centrally located in the vertebral body that arises from the posterior wall and infiltrates the cancellous bone, invading the epidural space and expands in the paravertebral regions, possibly creating huge soft tissue myxoid masses.

- Myeloma is fully lytic and therefore almost always negative on ^{99m}Tc scan; however, a pathologic fracture can occur early in the disease, giving a positive result on a ^{99m}Tc scan.
- Much rarer are osteosarcoma, angiosarcoma, and Ewing's sarcoma.
- *Infection*: A lytic lesion involving a disc and the contiguous vertebral bodies is strongly suggestive for infection. The suspect of spondylitis or spondylodiscitis is sometimes erroneously ignored. The incidence of these conditions in the normal population is not negligible; moreover, as cancer patients submitted or not to chemotherapy are presumably immunodepressed. This possibility should particularly be considered in the differential diagnosis of a metastatic disease.

Biopsy to provide material for histological study is the best and fastest way to a diagnosis, and frequently in case of metastases is also suggestive of the primary lesion: mucoid appearance for gastrointestinal tumors, clear cells for renal cancer, and small cells for lung cancer. However, biopsy can be avoided in cases of diffuse metastases in a patient with well-known carcinoma, or the incidence of metastatic disease at short distance after breast carcinoma simultaneous with increasing levels of specific biochemical markers. Additionally, the oncologist can request a biopsy if treatment has started without histological confirmation or if the lesion increases in size after treatment has begun.

A safe technique to perform a bone biopsy is with a trocar under CT guidance. This allows minimal soft tissue contamination and specimen sampling from the representative and viable portion of the tumor. Bone biopsy should be performed with a trocar rather than fine needle aspiration, in order to provide the pathologist with a sufficient quantity of specimen, which is representative of the tissue architecture.

Surgical Options

Refinement of the protocols for treating tumor patients has led to a progressive improvement in the prognosis for many tumor histotypes in terms of mean survival time. As a consequence, the interest is growing on symptomatic spinal metastases, particularly in patients without other evidence of disease, if severely affecting their quality of life.^{1,20} Historically, the role of surgery for spinal metastases was largely confined to decompression of the compressed spinal cord and/or nerve roots.²¹⁻²⁴ Laminectomy alone has been proven to be mediocre in outcome and not more

beneficial than radiotherapy alone.^{24,25} Due to increasing patient expectations, in order to attempt complete local control and to provide the best functional results, more and more aggressive surgeries have been proposed for the treatment of spinal metastases.^{4,26,27} Conversely, to reduce the surgical morbidity especially in patients with poor general condition, less invasive surgical techniques have been developed, often combined with radiotherapy or other local tumor ablation techniques.

Commonly accepted indications for surgery include cord compression, pathologic fracture, intractable pain, and spinal instability caused by the lesion.²⁸ What is still a matter of discussion are the indications of the different techniques. The different surgical options are presented.

Laminectomy and Fixation

Laminectomy is targeted to decompress the spinal cord: It does not necessarily include tumor removal, but complete decompression is achieved by the removal of at least part of the tumor mass invading the canal. If the tumor invades the vertebral body, surgical removal of posterior elements reduces the stability. Fixation is therefore mandatory to prevent collapse and secondary further cord compression. Rades²⁹ found that patients with metastatic spinal cord compression had improved functional outcomes, particularly those patients with an unfavorable primary tumor, from decompressive surgery plus stabilization compared to laminectomy and radiotherapy. Bilsky³⁰ from a systematic review considering 19 articles out of >80,000 titles concluded that decompression and instrumentation are the treatment of choice of epidural cord compression from solid tumor metastases.

In 2005, Patchell³¹ published the only prospective, randomized, multi-institutional trial comparing external beam radiation (30 Gy in 10 fractions) to decompressive surgery and instrumentation followed by external beam radiation therapy in 101 symptomatic patients with spinal cord compression. The primary tumor histology was lung carcinoma in 26 patients with 13 in each arm. Patients undergoing surgery and radiation therapy had statistically significant improvement compared to radiation alone in terms of preservation of neurologic function and pain relief. Notably, 57% of patients in the radiation arm maintained ambulation, but the duration was only 13 days compared to ambulation until death (122 days) in the surgical arm. No patient in the radiation group recovered ambulation without surgery.

There is further evidence that this surgical technique performed before radiation therapy results in improved neurologic outcomes and fewer wound complications rather than performed after.³² The morbidity of this technique can be reduced by percutaneous implant of the pedicle screws (Figs. 119.7A to E) and by microscopic or endoscopic decompression.

Tumor Debulking

Tumor removal, not only to decompress the cord but also to substantially reduce the tumor mass, is performed for local control when no other treatment is effective or available. This surgical procedure can be performed by anterior approach³³ or by posterior approach³⁴ or by combination, according to tumor extension and the need for a complete 360° reconstruction, providing the patient with appropriate sagittal balance. The morbidity of this technique can be reduced by percutaneous implant of the pedicle screws combined by microscopic tumoral excision or by tumor ablation by radiofrequency (Figs. 119.7A to E) or electroporation.

Selective Arterial Embolization

Selective arterial embolization (SEA) is an angiographic procedure performed to embolize the artery feeding a tumor. Its role as a therapeutic agent is questionable in metastases, though it plays a major role in the treatment of aneurysmal bone cyst and similar conditions.³⁵ The purpose of SEA in the treatment of metastases is to ischemize the tumor and decrease blood flow to the mass before intralesional excision. Only a few publications have succeeded to provide evidence supporting its use,³⁶ but expert opinions support a correctly performed SAE to significantly reduce the intraoperative blood loss, making surgery safer, less morbid and more effective, as the surgeon is able to remove much more volume of tumor than under profuse bleeding.³⁷⁻³⁹

The limit of this procedure in the spine is represented by the possible anastomosis of the tumor vascularization with the spinal cord arterial supply. The various interventions designed to embolize the tumor feeding arteries, such as particles, glue or spirals, could embolize the arteries supplying the cord, provoking an irreversible paralysis. The angiographer will necessarily perform a careful study of the vascular supply of the cord in order to detect possible anastomosis with the tumor vascularization to avoid this complication.

En Bloc Vertebrectomy

En bloc tumor removal is the treatment of choice of primary low-grade malignant tumors and must be considered exceptional for metastases.^{40,41} It is a technically demanding procedure with a high risk of complications.⁴² Once the criteria of feasibility are satisfied,⁴³ the indication in a metastatic lesion must be justified. A reasonable goal is to achieve the complete local control in a patient with a high chance of long-term survival.

Tumors with no or low sensitivity to other treatments, such as metastatic renal carcinoma and sarcomas, are the best indication, particularly if they are hypervascularized and intralesional surgery⁴⁴ carries a high risk of life-threatening bleeding during surgery. Bilsky in an exhaustive systematic review of the literature concluded that following en bloc resection, 40 cases of metastases from renal cell carcinoma experienced 7.5% local recurrence at a median follow-up of 16 months.³⁰

Vertebroplasty

Vertebroplasty is a minimally invasive technique, considered an interventional radiology technique, which consists of the injection of polymethylmethacrylate (PMMA) cement inside the vertebral body by percutaneous approach under radioscopic control or under CT guidance.²² Performed for the first time in 1984 by Deramond⁴⁵ in France for the treatment of an aggressive angioma of C2, it has undergone considerable development, extending its indications to the treatment of vertebral metastases. However, tumors inside the vertebrae are mostly solid, and if PMMA is injected in the vertebra without having first destroyed or removed the tumor, it may enter the vertebral canal or spread around the vertebra, potentially disseminating tumor cells.⁴⁶ Polymethylmethacrylate has no proven antitumoral effect, and if the tumor does not respond to adjuvant therapies, it will continue to grow. Cavitation by RFA followed by filling this void with PMMA seems a reasonable option. Finally, it should be noted that the morbidity associated with vertebroplasty, although low, is not negligible.⁴⁷

Vertebral augmentation by PMMA injection appears to be an interesting option in patients with diffuse disease to stabilize the spine and relieve pain, in situations where local tumor control is not a major concern. Absolute contraindications to vertebroplasty include the complete erosion of the posterior wall, retropulsion of fracture elements, and cord compression by tumoral mass expanding

in the canal. In these cases when PMMA is injected and pressurized, it can extravasate from the vertebral body and encroach upon the canal compressing the spinal cord; decompressive surgery should be best performed if the risk of spinal cord compression is high.

Staging and the Decision-Making Process

Once a metastatic lesion is diagnosed, even if solitary, it necessarily implies systemic disease. The decision-making process should start from a systematic evaluation of the patient and the disease. The medical oncologist holds a prominent role in estimating a reasonable life expectancy, as does the anesthesiologist, in assisting the determination of the patient to tolerate different surgical treatments. To select the most appropriate local treatment for each patient, the cost-benefit ratio of any surgical, chemotherapeutic, or radiotherapy treatment, in terms of morbidity versus established advantages, must be considered.^{1,26,48}

Speak the same language: In this multidisciplinary approach, the first requirement is to “speak the same language” in order to weigh every element on the same scale. Ideally, a scoring system or an algorithm could be helpful in order to make any decision reproducible and correlate treatment morbidity with expected outcome. A deterioration of neurological function can be recognized, the severity of pain can be mitigated, a pathologic fracture can be treated, but the identification and prevention of impending fracture remain a major issue. The concept of spinal instability is critical in this decision-making process. Instability, as the result of tumoral erosion, differs from the result of traumatic injuries, due to bony and ligamentous involvement, bone quality and the potential for healing, and therefore requires different criteria. The Spine Oncology Study Group, an international multidisciplinary group of spine oncology experts, has defined “spine instability” as (a) loss of spinal integrity as a result of a neoplastic process that is associated with movement-related pain, (b) symptomatic or progressive deformity, and/or (c) neural compromise under physiologic loads. They have proposed the Spine Instability Neoplastic Score based on patient symptoms and radiographic criteria to predict spine stability of neoplastic lesions.⁴⁹ This system includes spinal location of the tumor, type and presence of pain, bone lesion quality, spinal alignment, extent of vertebral body collapse, and posterolateral spinal element involvement.

Qualitative scores were assigned based on relative importance of particular factors gleaned from the literature and refined by expert consensus (Table 119.1).

Outcome evaluation: Outcome evaluation should be compared with the patient status at diagnosis. A largely accepted system to evaluate the quality of life is Karnofsky score,⁵⁰ a subjective measure of how well the patient is doing (see Table 119.2). It is useful to identify trends over time, as well as to see fluctuations in patient satisfaction throughout the disease process. The Karnofsky score is also sometimes used as a criterion for entrance into a clinical trial.

Scoring system: Several preoperative scoring systems have been proposed to classify patients affected by spine metastases and help guide the appropriate treatment. The various different classification schemes are justified by the frequency of the disease and need to standardize the selection of the appropriate treatment to show favorable outcomes and improve the quality of life.

Harrington classification, 1986: This was the first important attempt to stage patients with spine metastases.⁵¹ It divides patients who have spinal metastases into five categories, depending on the extent of neurological compromise or bone destruction:

- Class I: No significant neurological involvement
- Class II: Involvement of bone without collapse or instability
- Class III: Major neurological impairment (sensory or motor) without significant involvement of bone
- Class IV: Vertebral collapse with pain due to mechanical causes or instability but without significant neurological compromise
- Class V: Vertebral collapse or instability combined with major neurological impairment.

With this classification schema, the class guides the treatment. Class I or II patients generally obtain relief from pain by chemotherapy or other medical treatment, or, if unsuccessful, from local radiation therapy. Patients in Class III usually respond to treatment with radiotherapy alone. If the neurological compromise is acute, the radiotherapy should be augmented by systemic administration of steroids. Given that vertebral collapse is present in both class IV and V, these groups of patients are not likely to improve from irradiation alone, regardless how radiosensitive the underlying malignancy may be; surgical intervention is indicated.

Table 119.1: The SINS classification according to Fisher et al.⁴

	Score
Location	
Junctional (occiput C2, C7-T2, T11-L1, L5-S1)	3
Mobile spine (C3-C6, L2-L4)	2
Semirigid (T3-T10)	1
Rigid (S2-S5)	0
Pain*	
Yes	3
Occasional pain but not mechanical	1
Pain-free lesion	0
Bone lesion	
Lytic	2
Mixed (lytic/blastic)	1
Blastic	0
Radiographic spinal alignment	
Subluxation/translation present	4
De novo deformity (kyphosis/scoliosis)	2
Normal alignment	0
Vertebral body collapse	
> 50% collapse	3
< 50% collapse	2
Not collapse with > 50% body involved	1
None of the above	0
Posterolateral involvement of spinal elements[‡]	
Bilateral	3
Unilateral	1
None of the above	0

*Pain improvement with recumbency and/or pain with movement/loading of spine

‡Facet, pedicle, or costovertebral joint fracture or replacement with tumor.

Asdourian classification, 1990: The classification scheme proposed by Asdourian⁵² suggests surgical intervention in cases where increasing vertebral collapse (type IIB, type IIIA-B, type IV) corresponded to progressive instability and cord compression.

Bauer classification, 1995: Bauer proposed a scoring system suggesting “radical” surgery for patients with solitary metastasis without pathologic fracture, from primaries with relatively good prognosis without visceral localization (group C).⁵³

Sioutos classification, 1995: Sioutos⁵⁴ proposed that survival after surgical treatment of spine metastasis is affected by preoperative neurological status, primary tumor histotype and the number of involved vertebrae, but not by localized spread of the disease nor the age of the patient.

Katagiri classification, 2005: Katagiri⁵⁵ proposed a scoring system considering several prognostic factors: performance status, histotype, the presence or absence of visceral and brain metastases, multiple spine metastases, and previous courses of chemotherapy. A study published in the same year by Var der Linden⁵⁶ supported the Katagiri Classification by stating that surgery is indicated only in patients (group C) with favorable histotype, good performance status and without visceral metastases.

Rades classification, 2008: Rades⁵⁷ proposed a scoring system considering histotype, bone and visceral metastases, interval from primary tumor treatment and onset of spine metastasis, and neurological symptoms.

Tokuhashi classification, 1990: Tokuhashi⁵⁸ proposed a system that assesses the prognosis of metastatic spine tumors based on the six parameters given further:

Table 119.2: Karnofsky performance status scale KPS scale.

Able to carry on normal activity and to work; no special care needed	100	Normal no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed.	70	Cares for self; unable to carry on normal activity or to do active work
	60	Requires occasional assistance, but is able to care for most of his personal needs
	50	Requires considerable assistance and frequent medical care.
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance.
	30	Severely disabled; hospital admission is indicated although death not imminent
	20	Very sick; hospital admission necessary; active supportive treatment necessary
	10	Moribund; fatal processes progressing rapidly
	0	Dead

1. General condition
2. Number of extraspinal bone metastases
3. Number of metastases in the spine
4. Metastases to the major internal organs (lungs, liver, kidneys, and brain)
5. Primary site of the cancer
6. Severity of spinal cord symptoms.

In the scoring system, each parameter ranges from 0 to 2 points. The total score obtained for each patient can be correlated with and predict the prognosis. Excisional surgery is suggested for those cases who scored >9 points, while palliative surgery is indicated for those who scored <5 points. In 2005, Tokuhashi⁵⁹ revised his system, giving more importance to the primary site of cancer (0–5 instead of 0–2). This improved the predictivity of the prognosis from 62% to 81%. In patients with a total score of 12 or more (predicted survival period 1 year or more), excisional procedures are proposed. In patients with a total score 9–11, excisional procedures are indicated in a single lesion without metastases to the major internal organs. Palliative procedures are suggested in all other cases. Surgery was not indicated in patients with a predicted survival period of 6 months or less (score 0–8).

Tomita classification, 2001 (see Table 119.3): Tomita²⁷ proposed a scoring system for spinal metastases based on three prognostic factors:

1. Grade of malignancy (slow growth, 1 point; moderate growth, 2 points; rapid growth, 4 points)
2. Visceral metastases (no metastasis, 0 point; treatable, 2 points; untreatable, 4 points)
3. Bone metastases (solitary or isolated, 1 point; multiple, 2 points).

These three scores are added together to give a total score ranging from 2 to 10. A score of 2–3 points suggests treatment with wide or marginal excision for long-term local control; 4–5 points suggest intralesional excision for mid-term local control; 6–7 points propose palliative surgery for short-term palliation; and 8–10 points indicate nonoperative, supportive care.

These systems are limited because they guide treatment strategy based on arbitrary scores attributed to selected parameters. The benefit of these classifications is their attempt to standardize treatment and suggest the appropriate treatment. The score attribution is validated retrospectively on the outcomes studied. In certain schema, equal importance is therefore given to the various parameters, which may not be valid, as Tokuhashi's modification exemplifies. For example, the histotype of the primary tumor and the general condition of the patient have the same influence on the final score and therefore on the treatment selection.

A proposed algorithm for decision-making process: This algorithm^{48,60} was proposed as an alternative to these

Table 119.3: Classification of vertebral involvement by metastatic disease proposed by Tomita et al.²⁷

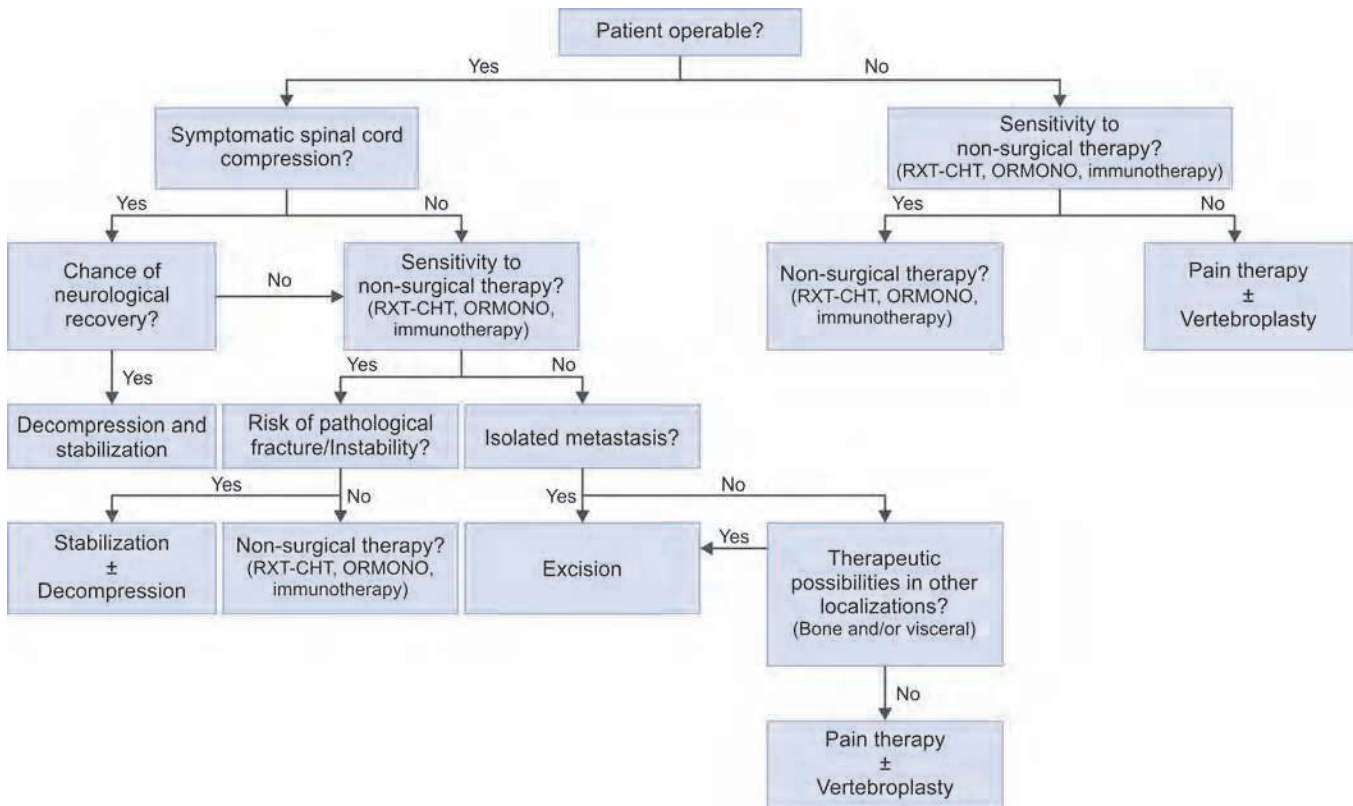

Intra-compartmental	Extra-compartmental	Multiple
Type 1 Vertebral body	Type 4 Epidural extension	Type 7
Type 2 Pedicle extension	Type 5 Paravertebral extension	
Type 3 Body-lamina extension	Type 6 2–3 vertebrae	

scoring systems, considering that the decision-making process for spine metastases is individualized. Each patient follows his or her “personal” sequential process that does not necessarily consider each of the parameters at every time point, as some may be irrelevant at certain time points in the decision-making process. For example, a patient in poor general conditions with a high ASA (American Society of Anesthesiologists) score⁶¹ is not a candidate for surgery irrespective of the histotype of the primary tumor or the number of secondary localizations. For these patients, the most important parameter will therefore be the sensitivity of the tumor histotype to adjuvant treatment. In the same way, a patient with acute and worsening spinal cord damage will undergo emergency palliative decompression and stabilization surgery even for patients with increased ASA scores. Surgical fixation and decompression can be performed by minimally invasive procedures or through standard open surgical techniques (see Fig. 119.3). This should be decided on a case-by-case basis according to the surgeon’s training and preferences. In some cases, such as hepatocellular carcinoma, evidence exists for tumor ablation by radiofrequency (see Figs. 119.7A to E).

The parameters considered in this algorithm are shown in Flowchart 119.1 and summarized as the following:

1. General condition and the ASA⁶¹ score
2. Sensitivity of the primary tumor to chemotherapy and radiotherapy
3. Neurological symptoms

4. Pathologic or impending fracture
 5. Systemic disease and possible treatment of visceral metastases.
- Once a spine metastasis is diagnosed, the decision-making process should start from the anesthesia assessment. If the patient cannot safely undergo a surgical procedure, the sensitivity of the tumor histotype to nonsurgical treatments (chemotherapy, hormonal, immunologic, radiotherapy) is considered. If the tumor does not respond to any form of treatment, the only option for the patient is pain control. Vertebroplasty can be considered for palliative pain control, and the patient should be referred to a pain management specialist.
- Any treatment theoretically determined on a scoring system may not necessarily be applicable and may be “over-ruled” if the ASA⁶¹ score is prohibitive or if there are surgical contraindications for any reason independent from the disease we are dealing with.
- Neurologic compromise present:* If the patient can safely undergo surgery, the first element to be considered is the neurological status. If neurological compromise is present, the possibility of recovery is evaluated on the duration from the onset of symptoms.
- If no neurological recovery of the patient is possible as paraplegia or tetraplegia are present for >48–72 hours, sensitivity to nonsurgical treatments is considered together with surgical stabilization to minimize pain, even for sitting and transfers.

Flowchart 1: Treatment of spinal metastases.

- If the paralysis is incomplete and worsening, emergency decompression and fixation is the recommended treatment of choice.

Neurologic compromise absent: If no neurological symptoms are present, the decision-making process begins by considering the sensitivity to medical oncology treatments and radiotherapy. The local effect of the metastatic deposit in terms of stability must be considered as well.⁴⁹

- If the tumor histotype is not sensitive to radiation nor chemotherapy and the metastasis is solitary, resection of the lesion is proposed. Resection of the tumor may be performed by curettage (debulking, intralesional excision) or en bloc resection. En bloc resection should be performed when extension and location allow feasibility of such treatment⁴³ and for hypervascularized metastases (see Figs. 119.6A to F) as morbidity of intralesional excision due to intraoperative bleeding of vascular metastases can be significant.⁴⁴ The role of stereotactic radiosurgery has similar indications.^{30,62}
- If the metastases are multiple, a surgical plan including both fixation to prevent collapse and decompression

to prevent spinal cord damage is suggested. In case of disseminated disease or if stabilization is not technically feasible, surgical intervention could consider vertebroplasty for pain relief.

- Impending or assessed pathological fracture is decisive in choosing between surgical treatment with decompression and stabilization (see Figs. 119.4A to D) or nonsurgical treatment only. This case is particularly demonstrative of the validity of this algorithm in terms of multidisciplinary approach, by avoiding the morbidity of an en bloc resection, as would be proposed by the Tomita and Tokuiashi scoring systems, while achieving local control of the disease.

This algorithm could represent a valid guide for the decision-making process in the treatment of spine metastases. It is centered on each patient's requirements to allow the best quality of life and is based on a multidisciplinary approach. The proposed algorithm seems effective as an interdisciplinary guidelines.

Prospective studies are necessary to assess the validity, the reliability, and the reproducibility of this algorithm. Furthermore, the continuous progress of medical

oncology and radiotherapy will possibly propose newer, less morbid, and more effective treatments in the future, which can be included in the algorithm.

ACKNOWLEDGMENT

The authors are indebted to Carlo Piovani for his valuable work as archivist and media designer.

KEY POINTS

- The spine is a frequent site of bone metastases from carcinomas. Back pain in a patient with a history of carcinoma warrants investigation to exclude a metastasis. Both quality of life and survival can be seriously threatened by a spine metastasis.
- Magnetic resonance imaging is the imaging technique of choice to evaluate known spine metastasis and detect possible further asymptomatic lesions. Histology, best performed by CT-guided trocar biopsy, is mandatory to diagnosis and, thus, proposes specific treatments. The behavior of metastasis and sensitivity to treatment is related to the primary tumor histotype.
- Surgical options are *palliative procedures* (laminectomy with necessary fixation, fixation alone, vertebroplasty), *debulking* (curettage, intralesional excision), and *en bloc resection*. Minimally invasive techniques are improving functional results while reducing morbidity and pain.
- A multidisciplinary team, including medical oncology, radiation oncology, surgical oncology, and pain management specialist, should be involved in the care of each patient, discussing cost-benefit ratio of possible therapies and evaluating the possibility of combined and staged treatments.
- Scoring systems and algorithms have been proposed to correlate clinical situations and prognosis and guide the treatment to standardize the treatment to obtain the best outcome.

Sundaresan N, Schmidek HH, Schilber AL, Rosenthal DI (Eds). *Tumors of the Spine: Diagnosis and Clinical Management*. Philadelphia: W.B. Saunders; 1990. pp. 473-87.

The surgeon who first popularized the en bloc resection by posterior approach here describes the original technique. The most important details are: extrapleural release of the vertebral bodies by digital dissection, osteotomy by gigli saw and osteotomes with careful dura protection, posterior fixation based on pedicle screws.

Fisher CG, DiPaola CP, Ryken TC, et al. A novel classification system for spinal instability in neoplastic disease. An evidence-based approach and expert consensus from the spine oncology study group. *Spine*. 2010;35:E1221-9.

This article presents first the Spine Oncology Study Group (SOSG) definition “spine instability” in spine tumors as loss of spinal integrity associated with movement-related pain, symptomatic or progressive deformity, and/or neural compromise under physiologic loads. A scoring system is proposed (Spine Instability Neoplastic Score: SINS) based on patient symptoms and radiographic criteria to predict spine stability of neoplastic lesion. The elements include spinal location of the tumor, type and presence of pain, bone lesion quality, spinal alignment, extent of vertebral body collapse, and posterolateral spinal element involvement. Qualitative scores are assigned based on relative importance of particular factors gleaned from the literature and refined by expert consensus.

Tokuhashi Y, Matsuzaki H, Oda H, et al. A revised scoring system for preoperative evaluation of metastatic spine tumor prognosis. *Spine*. 2005;30:2186-91.

In this article, the scoring system proposed in 1990—based on general conditions, number of extraspinal bone metastases, number of metastases in the spine, metastases to the major internal organs, primary site of the cancer and severity of spinal cord symptoms—is submitted to a revision. More importance is given to the primary site of cancer (0–5 instead of 0–2). The predictivity of the prognosis improved from 62% to 81%. In patients with a total score of 12 or more (predicted survival period 1 year or more), excisional procedures are proposed. In patients with a total score 9–11, excisional procedures are indicated; palliative procedures are suggested in all other cases. Surgery was not indicated in patients with a predicted survival period of 6 months or less (score 0–8).

Intradural Intramedullary and Extramedullary Tumors

INTRODUCTION

Intradural tumors are among the rarest of neoplastic conditions. Due to the rarity of these tumors, diagnosis and management are challenging. Even for the spine surgeon in a busy center, intradural tumor resection is an infrequent operation, and therefore the potential for research and trials aimed at improving outcomes is especially difficult.¹ Despite this, surgery has the potential to reverse a patient's neurological deficit and offer an oncological cure.

The treatment of intradural tumors combines the best of spine, oncological, and microneurosurgical principles. It requires a team-oriented and multidisciplinary approach involving surgeons, oncologists, neurologists, rehabilitation physicians, radiologists, pathologists, and allied health professionals. Understanding the pathology of each tumor type is especially important in that it guides surgical management in establishing the correct surgical plane, extent of resection, and subsequent adjuvant treatment.

EPIDEMIOLOGY

Spinal cord tumors are rare. They represent only about 0.5% of newly diagnosed tumors¹ and account for 4–8% of all central nervous system tumors.² They have an overall incidence of 0.74 per 100,000 person-years (0.77/100,000

in females and 0.70/100,000 in males). To put this in perspective, the overall cancer incidence in the United States was 423.9/100,000 in females and 556.7/100,000 in males between 2000 and 2004.³ In general, intramedullary tumors are more common in males, whereas intradural-extramedullary tumors are more common in females.⁴ The individual gender distribution for the main tumor subtypes is shown in Figure 120.1.

Approximately two-third of intradural tumors are extramedullary,^{5–7} the most common of which is a meningioma that accounts for 29% of primary spine tumors.⁷ The most common intramedullary tumor in the adult population is an ependymoma that accounts for 23% of primary spine tumors⁷ (Fig. 120.2). Ependymomas have been shown to have an increasing incidence, whereas the incidence of astrocytomas has remained stable.²

CLASSIFICATION

Tumors are classified by their location (Figs. 120.3A to C). This historical classification was based on the findings of myelograms⁸ but is still used today in the magnetic resonance imaging (MRI) era. The first distinction to make is whether a tumor is intradural or extradural in location. If intradural, the next distinction is whether the

Fig. 120.1: Gender distribution of spinal intradural tumor.

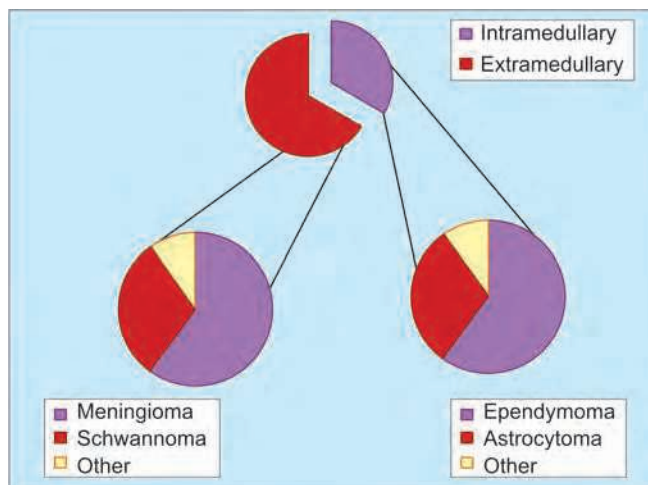

Fig. 120.2: Incidence of tumors by location and pathology.

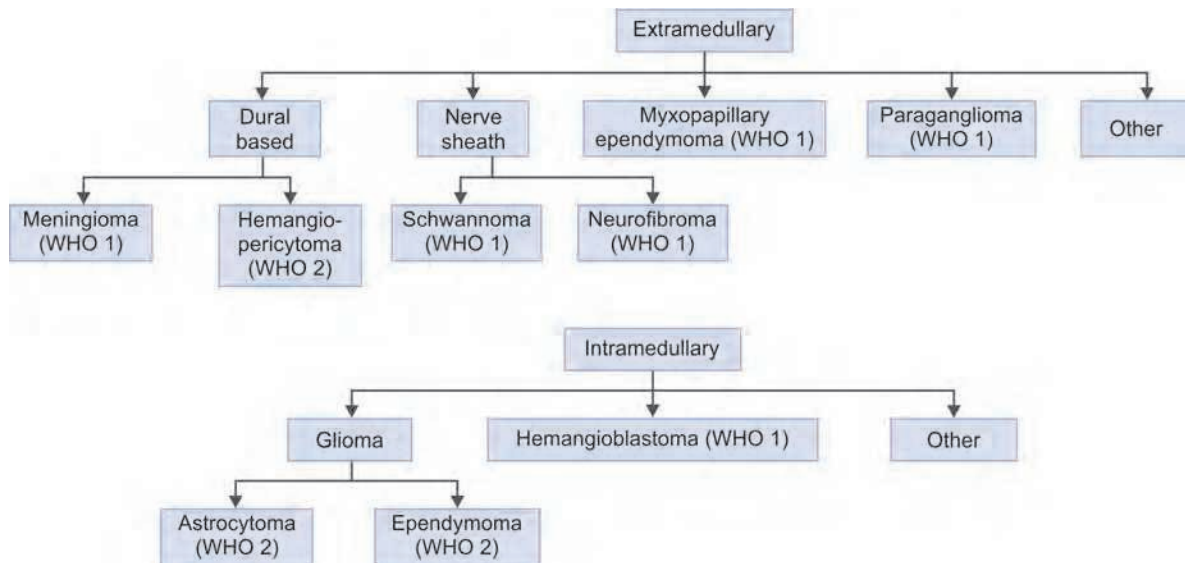

Figs. 120.3A to C: Illustration of (A) intramedullary, (B) intradural extramedullary, and (C) extradural tumors.

tumor is within the parenchyma of the spinal cord, termed *intramedullary*, or external to it, termed *intradural extramedullary*. In some cases, tumors may extend between locations, such as an exophytic tumor of the cord, which may be both intra- and extramedullary; or schwannoma that may be a combination of intradural and extradural as it follows the course of the exiting nerve root. Intradural spinal cord tumors are further classified pathologically (Flowchart 120.1). Accordingly tumors will be discussed below by histopathological subtype.

PATHOLOGY

Understanding tumor pathology provides invaluable information that guides both surgical and postoperative management. The tumor cell of origin will dictate the surgical plane as well as influence the surgical approach and extent of resection. For example, an astrocytic glioma of the spinal cord will more likely be a diffusely infiltrating tumor, without a good surgical plane and hence may not be completely resectable in distinction with an ependymal glioma, which is usually well circumscribed.

Flowchart 120.1: Classification of tumors by location and pathological subtype.

Intradural Extramedullary Tumors

Meningioma

These tumors are dural based, arising from the arachnoid cap cell that is a nonneuroepithelial progenitor cell.⁹ They are most common in the thoracic spine^{9,10} and in females with some series showing a female preponderance approaching 90%.¹⁰ The majority of tumors are benign and characterized as World Health Organization (WHO) grade 1; however, atypical (WHO grade 2) and anaplastic (WHO grade 3) tumors occur and show a male predominance.

There are nine histomorphological subtypes of WHO grade 1 meningiomas, which accounts for their diverse appearance. These are meningothelial, fibroblastic, transitional, angiomatous, microcystic, lymphoplasmacyte-rich, secretory, metaplastic, and psammomatous. The latter is the most common in the spine and is characterized by frequent psammoma bodies. These are irregular-shaped collections of osteoid that can become confluent and calcify and occasionally form bone.¹⁰ While calcification is common microscopically and can be detected radiologically if sufficiently abundant, grossly calcified meningiomas occur only in up to 5% of cases.¹¹ Another typical histological feature is that of whorl formation of the intervening neoplastic cells.

The presence of certain histological features including increased mitotic activity can upgrade the tumor grade to

atypical or WHO grade 2. Chordoid and clear cell variants are automatically assigned a grade 2. Obviously malignant cytology, or a marked increase in mitotic activity or papillary or rhabdoid subtypes, designates a meningioma as malignant¹⁰ (WHO grade 3). Proliferation indices have been shown to correlate with tumor growth.¹⁰ Immunohistochemical staining is invariably positive for EMA, however, with decreasing reactivity in higher-grade tumors.¹⁰

Meningiomas commonly are positive for sex hormone receptors: 88% have progesterone, 40% estrogen, and 39% androgen receptors.¹⁰ The presence of estrogen receptors may be associated with aggressive histological characteristics.¹²

Meningiomas typically have aberrations involving chromosome 22¹³ and are a hallmark feature of neurofibromatosis type 2 (NF2) whose locus is located on chromosome 22q.¹⁰ Apart from neurofibromatosis, there are other familial conditions in which patients develop multiple meningiomas, and in these the SUFU mutation has been implicated.¹⁴ Other affected genes in meningioma include 1p, 14q¹³ and DAL.¹⁰

Radiation-induced meningiomas are the most common form of radiation-induced neoplasms.¹⁵ These tumors tend to be more histologically aggressive and associated with chromosomal aberrations in particular at loci 1p and 6q.¹⁰

Hemangiopericytoma

Hemangiopericytomas are radiologically similar but histologically distinct to meningiomas. They therefore present

a common radiological differential diagnosis to meningioma, although they occur much more rarely.¹⁶ They are mesenchymal cell tumors composed of a highly cellular and vascular stroma with characteristic “Staghorn” appearance of vasculature.¹⁰ Hemangiopericytoma are a locally aggressive tumor with a propensity for recurrence and are classified as WHO grade 2.¹⁶

Peripheral Nerve Sheath Tumors

There are two main types of peripheral nerve sheath tumors: schwannomas and neurofibromas. The main distinction is that schwannomas arise from and contain neoplastic Schwann cells, whereas neurofibromas may contain all the elements of a peripheral nerve, including perineural cells, axons, fibroblasts, and Schwann cells.¹⁷ These tumors arise from the nerve root before leaving the dural sac in 60–80% and a further 10% arise from the nerve as it exits the dural sac in its nerve sleeve.¹⁸ This may give rise to dumbbell morphology that has been classified based on location.¹⁹ Schwannomas usually arise from the dorsal sensory part of the nerve root.²⁰

They are both graded as WHO grade 1 tumors. However, malignant peripheral nerve sheath tumors occur in a few cases.¹⁸ They account for about 5% of soft-tissue tumors.¹⁰ The majority arise from neurofibromas; about half from plexiform neurofibromas in patients with neurofibromatosis type 1, but they may also arise de novo.¹⁰ Very rarely do they arise from the malignant transformation of a schwannoma.^{10,17}

Schwannoma

This is a well-encapsulated tumor that arises from neoplastic Schwann cells.¹⁰ It is characteristically composed of two distinct patterns known as Antoni A and B. Areas of densely packed cells with areas of cellular palisading are the Antoni A pattern, whereas loosely arranged cells often with intervening lipid are the Antoni B pattern. The Antoni A palisading pattern often forms a characteristic Verocay body that resembles the wooden spindles used in textile spinning.¹⁷ The preponderance of Antoni A relative to B shows both inter- and intratumor variability. Cellular schwannomas are a histological variant composed of predominantly Antoni A regions, typically lacking Verocay bodies.¹⁰ This variant has a higher recurrence rate.¹⁰ Immunohistochemistry is typically positive for S100 and Leu 7.¹⁰ Inactivating mutations within the NF2 gene are found in up to 60% of schwannomas.¹⁰

Neurofibroma

These tumors contain a combination of nerve fibers, collagen fibers, fibroblasts, and Schwann cells.¹⁰ The latter typically being smaller than the Schwann cells found in schwannomas. Collagen fiber appears variably, but typically they give a “shredded carrot” appearance.¹⁰ Blood vessels within neurofibromas typically are not hyalinized, unlike in schwannomas.¹⁰ They also contain less basement membrane proteins²¹ than schwannomas reflecting less immunohistochemical expressivity for such markers as well as S100.

Myxopapillary Ependymoma

This tumor is almost exclusively localized to the region of the termination of the spinal cord, specifically in the filum terminale, conus medullaris or cauda equina. It is a slow-growing tumor, classified as a WHO grade 1 tumor, and typically occurs in young adults with a 2.2:1 male to female ratio.¹⁰ Patients therefore typically present with insidious onset of back pain and may have mixed upper and lower motor neuron signs as well as bowel, bladder or sexual dysfunction.

Histologically, it is characterized by columnar or cuboidal cells arranged with papillary architecture, containing a mixoid stroma that typically stains with alcian blue. It is generally positive for glial fibrillary acidic protein (GFAP) and S100 immunohistochemical stains but negative for cytokeratin.¹⁰

Paraganglioma

Paraganglioma is a neuroendocrine tumor, arising from neural crest cells. It uncommonly occurs within the spine but has a predilection to the cauda equina region. They, however, only account for around 3.5% of tumors in this region. They have a 1.4:1 male to female ratio. Histologically they are composed of type 1 or Zellballen cells, surrounded by a layer of sustentacular, type 2 cells. There are only case reports of endocrinologically active cauda equina paragangliomas.¹⁰

Metastasis

Intradural metastases are rare. The vast majority of spinal metastatic disease originates from the vertebral bodies and is thus extradural. Intradural metastatic disease may either be extra ($\approx 4\%$) or intramedullary ($\approx 2\%$). The pattern of transmission may either be direct extension, haematogenous or via the cerebrospinal fluid (CSF), causing the so-called drop metastasis. Primary intracranial tumors can metastasize to the lumbar cistern that way.

Intramedullary Tumors

Glioma

Glial cells are the supporting cells of the central nervous system and are composed of ependymal cells, astrocytes, and oligodendrocytes. Tumors can occur from any of these cell types; however, the latter rarely occurs in the spinal cord.^{10,22}

Astrocytoma

Astrocytomas originating in the spinal cord increase in tumor grade much less frequently than their cranial counterpart:²³ 75% are low grade (WHO grade 2)^{24,25} of which the diffuse fibrillary type is the most common.²⁵ Pilocytic astrocytoma (WHO 1 grade) accounts for 11% of pediatric spinal cord tumors.¹⁰ It is characterized by cyst formation containing a biphasic pattern of cells with compact bipolar cells associated with Rosenthal fibers and loose textured multipolar cells with microcysts.¹⁰ Rosenthal fibers are corkscrew-shaped intracytoplasmic inclusions.²⁶ Diffuse astrocytoma is characterized by neoplastic fibrillary astrocytes with nuclear atypia but the absence of mitosis. They may contain reactive gemistocytic astrocytes and microcysts.¹⁰ Their borders are difficult to delineate unlike pilocytic astrocytomas.²⁷ The malignant variant anaplastic astrocytoma, WHO grade 3, and glioblastoma WHO grade 4 account for up to 15–1.5% of tumors respectively⁸ and have a very poor prognosis.²³ Immunohistochemical staining is consistently positive for GFAP.¹⁰ TP53 mutations are a genetic hallmark of astrocytoma and are present in >60% of cases.¹⁰

Ependymoma

Ependymomas are typically slow growing and composed of neoplastic ependymal cells with well-demarcated borders. They are the most common histological subtype of intramedullary tumors in adults. They are most common in the cervical spine.²⁸ Some sources report an equal distribution between males and females,¹⁰ whereas others show a predilection for males.² They are typically classified as WHO grade 2 tumor; however, there is a rare anaplastic form that is graded as WHO grade 3. There are four histological subtypes—cellular, papillary, clear cell, and tanyctic; the latter being most prevalent in the spine.¹⁰

Ependymomas are characterized histologically as a cellular glioma with monomorphic nuclei. There may be

salt-and-pepper speckled chromatin and mitosis are rare or absent.¹⁰ A classic but rare feature is that the cells are either arranged in ependymal rosettes, with a tubular lumen,²⁹ or perivascular pseudorosettes; however, these are particularly rare in the tanyctic variant.¹⁰ Tanyctic ependymomas have cells arranged in fascicles that in some cases can be difficult to distinguish from astrocytomas. Immunohistochemistry will typically be positive for GFAP, S100, and vimentin as well as EMA in many cases.¹⁰ Ependymomas are a common manifestation of patients with NF2. There was thought to be an association with SV40 virus although this remains uncertain.¹⁰ The most common genetic aberration is on chromosome 22 in up to 30% of cases. MDM2 amplification is common in adult ependymomas.¹⁰

Hemangioblastoma

Hemangioblastomas are characteristically vascular tumors, often partially cystic with a mural nodule. The cell of origin remains elusive;¹⁰ however, vascular endothelial growth factor plays a role in tumor genesis.³⁰ They occur sporadically but are associated with Von Hippel-Lindau disease in 25% of cases.¹⁸ Histologically they are composed of lipid laden cells surrounded by a vascular network. Rosenthal fibers can be seen and necrosis is rare. Immunohistochemistry is positive for neuron-specific enolase and vimentin.³⁰

Other Rare Neoplasms

Ependymoma and astrocytomas comprise the overwhelming majority of spinal cord gliomas; however, rarely gangliogliomas and oligodendrogliomas can occur. These account for <1% and <50 cases, respectively.⁸ The first line of treatment for both is surgical resection.

Primary central nervous system lymphoma is also rare accounting for <1% of spinal cord tumors. They are typically B cell lymphomas. Diagnosis may be obtained by CSF cytology or biopsy. Treatment is nonsurgical with dexamethasone, methotrexate, and radiotherapy. Prognosis is poor.⁸

Dermoids, epidermoids, teratomas, and lipomas complete the differential diagnosis. Although often extramedullary, intramedullary extension at the level of the conus is not infrequent. Non-neoplastic lesions that could be mislabeled for tumors include vascular lesions (arteriovenous malformations, cavernomas), demyelinating diseases, and infections.

Fig. 120.4: Cross-sectional diagram of the spinal cord.

PERTINENT SPINAL CORD ANATOMY

The spinal cord begins caudal to the medulla oblongata, at the point where the first cervical nerve roots emerge,³¹ and ends as the conus medullaris, typically at L1-L2. In cross-section, the spinal cord contains a central H-shaped area of grey matter arranged in anterior, posterior, and lateral horns that are further subdivided into groups known as the lamina of Rexed³² (Fig. 120.4). Within the center of the grey matter is the central canal that is lined with ependyma being continuous with the cranial ventricular system. Surrounding the central grey matter is the white matter within which run the ascending and descending tracts. Understanding the arrangement of these tracts and their somatotopy is crucial as it explains the clinical presentation of tumors and safe surgical corridors to facilitate their resection. The following points will aid in understanding some of the clinical syndromes discussed later. The somatotopy of the motor or corticospinal tracts is such that the upper extremity tracts lie medial to the lower extremity. The anterior horn cell, from which the motor nerve emerges, is the point at which the manifestations of dysfunction change from upper to lower motor neuron. As the sensory nerve enters the dorsal horn, fibers that carry pain, temperature, and light touch decussate before ascending in the spinothalamic tracts. Those fibers that contain the modalities of deep touch and proprioception ascend uncrossed in the dorsal columns.

CLINICAL PRESENTATION

Tumors typically present in an indolent fashion. In rare situations, they can present with rapid or sudden deterioration, which may be due to tumor hemorrhage or cord infarction.^{33,34} Like with an intracranial mass lesion, the manifestations of spinal cord compression are proportional to both the size and rate of growth of a tumor.

Patients typically present due to either pain or loss of function, pain being the most common presentation.^{5,35} Once they do present, however, misdiagnosis of spinal cord tumors is unfortunately not uncommon.³⁶ It is important that the assessing physician has an index of suspicion for this rare condition. Differentiating intramedullary from extramedullary tumors may be difficult clinically but distinguishing features are shown in Table 120.1.

Patient evaluation should include assessment of the following:

1. **Pain:** Pain is the most common presenting symptom of an intradural tumor.³⁵ There are different types of pain that a patient may experience, including axial, radicular, central and in some cases distant pain such as headache.^{37,38} The character of the pain may provide a distinguishing clue to the clinician from the substantially more common type of back pain that results from degenerative disease. Pain may be worse at night or during recumbence unlike mechanical pain

Table 120.1: Distinguishing features of intramedullary from extramedullary tumors.

<i>Signs and symptoms</i>	<i>Intramedullary tumors</i>	<i>Extramedullary tumors</i>
Pain	Less common, and if present more likely funicular pain	Pain more common and often radicular in nature
Neurological signs	Lower motor neuron signs at the level of lesion (due to the involvement of anterior horn cells); upper motor neuron signs caudal to lesion	Upper motor neuron signs early due to extrinsic compression
Paresthesia	Ascending progression	Descending progression
Bowel/bladder	Dysfunction more common especially with conus lesions	Unusual

that is worse on movement. This may be due to venous congestion or dural distension, which is increased during recumbency. Another possible explanation is that the normal serum cortisol nadir at night results in increased tumor swelling. Patients may experience radicular pain due to tumor involvement of a nerve root. This pain may have dysesthetic qualities or be thoracic in location, both of which are rare in the initial presentation of radicular pain from disc disease. In some cases, such pain may manifest as intercostal or chest pain,³⁹ leading to pulmonary or cardiac investigations. Central pain, also called funicular pain, is a deep, poorly localized pain resulting from irritation of the spinothalamic or dorsal column fibers. It may be burning in nature with occasional stabbing like qualities. Such pain is indicative of spinal cord pathology such as an intramedullary tumor. Headaches can manifest from intradural tumors for a variety of reasons. They may be cervicogenic resulting from an upper cervical tumor that irritates the dura or nerve roots. They can result from changes in CSF dynamics⁴⁰ either from obstruction, such as from a foramen magnum tumor, or from increase in CSF protein, such as from a distant intradural tumor like a lumbar schwannoma.⁴¹ Patients with hydrocephalus will typically have morning headaches with associated nausea and vomiting. Rarely, elderly patients may present with the symptoms of normal pressure hydrocephalus, including gait disturbance, dementia, and urinary incontinence.⁴²⁻⁴⁴

2. **Function:** Weakness can be a manifestation of myelopathy, radiculopathy or a combination of both. A tumor causing myelopathy will typically produce weakness when there is dysfunction of >50% of upper motor neurons,³⁸ hence on presentation patients may have only subtle findings. Patients may present with difficulty ambulating due to proprioceptive dysfunction^{8,35,36} but have normal motor strength on examination, highlighting the need for thorough neu-

rological assessment.³⁶ In about 13% of patients, bowel or bladder dysfunction was the mode of presentation.¹⁴

3. **Neurological examination:** The neurological assessment is aimed at determining both the level of dysfunction and differentiating upper from lower motor neuron dysfunction. Longitudinal localization of the tumor is achieved by ascertaining the last level of normal function. Compartmental localization of the tumor is much more difficult and is confirmed by MRI. Suggestive features of intramedullary versus extramedullary tumors are in Table 120.1.

SYNDROMES

Anterior Cord

This syndrome spares the dorsal columns, hence, the patient will have a dissociated sensory loss, and specifically there will be motor weakness with loss of pain and temperature sensation but preservation of proprioception and vibration sensation. This syndrome can occur with ventral meningiomas or ventrally located intramedullary tumors. It occurs in its purest form with anterior spinal artery infarction.

Central Cord

This syndrome is most typical in cervical pathology and characterized by a preferential loss of upper extremity, especially hand motor function, with relative preservation of lower extremity function. This is due to the medial somatotopy of the upper extremity corticospinal tracts. It is most likely to occur with ependymoma or with tumor-associated syrinx. It also happens in trauma typically from hyperextension injuries.

Posterior Cord

This syndrome is due to dorsal column dysfunction resulting in a sensory and proprioceptive deficit. Despite

motor preservation, patients often have difficulty ambulating due to impaired proprioception. Patients who have dorsally located tumors may present with this syndrome, as will patients who have undergone a dorsal midline myelotomy.

Brown Sequard

This syndrome is classically due to hemisection of the spinal cord, which causes ipsilateral weakness and proprioceptive loss and contralateral pain and temperature loss. This is due to loss of the corticospinal and dorsal column tracts ipsilaterally and the spinothalamic tracts that decussate, respectively. Tumors involving the cord asymmetrically can produce these signs to a varying extent.

Conus Medullaris or Cauda Equina

Symptoms resulting from lesions of the cauda equina tend to have a more gradual onset compared with those originating in the conus.³² Pain is a prominent feature in cauda equina lesions and is often radicular in nature.³² Patients with lesions of the conus will more likely have bowel or bladder dysfunction and saddle paresthesia. They may have a more symmetric pattern of symptoms and dissociated sensory loss. Lesions of the conus may produce mixed upper and lower motor neurons signs with a preserved knee jerk reflex. The ankle jerk reflex is often absent from lesions in either location.

Other Clinical Features

It is rare for patients with primary tumors to present with constitutional features such as fatigue and weight loss; when present, this may be suggestive of a metastatic process.

Changes in spinal alignment manifested by loss of lordosis, scoliosis or torticollis may be apparent in up to one-third of patients with intramedullary tumors.⁴⁵ Horner's syndrome may be present, if the lateral horn cells in the cervicothoracic region are affected by a tumor.⁴⁵

Part of the assessment should include a review for manifestations of syndromes such as neurofibromatosis type 1. This includes a positive family history and a search for café-au-lait spots, neurofibromas, freckling of the armpits or groin, lisch nodules (iris hamartomas) as well as obtaining other imaging for optic nerve gliomas, sphenoid dysplasia, and plexiform neurofibromas.⁴⁶

DIAGNOSTIC TESTS

Plain radiographs may provide a clue to underlying pathology within the cord. There may be bony remodeling or reduction in the size of a pedicle from a peripheral nerve sheath tumor or the spinal canal may be enlarged at the level of a tumor. Radiographs may assist in operative planning; however, MRI should be performed in all cases as it provides the highest resolution imaging of the tumor and the spinal cord itself.

Historically, two lumbar puncture-based tests were used that are now largely replaced by imaging. It should be noted that lumbar puncture might be contraindicated, if there is an obstructive tumor, particularly at the craniocervical junction. Froin syndrome is viscous, proteinaceous, and hypercoagulable CSF due to stagnated CSF below the site of an obstruction.⁴⁷ Queckenstedt maneuver is performed by measuring CSF pressure and then by occluding the jugular veins, which will lead to a sharp rise in CSF pressure in the normal state; in cases where there is an obstruction, this rise will not occur.⁴⁸

Magnetic resonance imaging is the investigation of choice for evaluation of intradural tumors.²⁰ The first step in interpretation is to distinguish whether the tumor is intra- or extramedullary. An extramedullary tumor lies between the dura and the spinal cord and hence displaces the spinal cord; there will be a sharp interface with the CSF and an enlarged CSF space on the tumor side. The distinguishing features of common extramedullary tumors are shown in Table 120.2.

Meningiomas are most frequent in the older female population and are most commonly located in the thoracic spine. They are typically homogeneously enhancing, and may have foci of calcification and a dural tail (Figs. 120.5A to C). Nerve sheath tumors more commonly occur in the lumbar spine and may have a dumbbell appearance as they follow the course of the nerve root. They may be cystic and are more typically heterogeneously contrast enhancing (Figs. 120.6A to C). There may be remodeling of surrounding bone such as scalloping of the vertebral body, enlargement of the foramen or reduced pedicle size all of which are best appreciated on CT scan. Myxopapillary ependymomas are located at the conus region and may be hard to differentiate from a nerve sheath tumor (Figs. 120.7A to C).

Intramedullary tumors occur within the cord parenchyma and typically cause expansion of the cord. There may be an associated cord edema and syrinx particularly in the case of ependymomas. Ependymomas are the most com-

Table 120.2: MRI features of intradural extramedullary tumors.

Feature	Schwannoma	Meningioma
Incidence of spinal cord tumors	About 26%	About 32% (more common in female, and patients >60 years of age)
Location	Lumbar	Thoracic
T1 signal	Isointense	Hypoiso-intense
T2 signal	Markedly hyperintense	Hyperintense
Enhancement pattern	Heterogeneous	Homogeneous
Calcification	Rare	Common
Shape	Dumb-bell	Round
Other	May be cystic, have a foraminal or extradural component with bony remodeling best seen on CT	Dural tail

(MRI: Magnetic resonance imaging; CT: Computed tomography).

Figs. 120.5A to C: Typical appearance of a spinal meningioma.

mon intramedullary tumor and more frequently centrally located due to their origin from the ependymal lining of the central canal. They may have surrounding hemosiderin and are typically well demarcated, as are hemangioblastomas. Astrocytomas are in contradiction typically poorly demarcated and show heterogeneous contrast enhancement. Distinguishing features are shown in Table 120.3.

Imaging the entire neuro-axis may be required, especially when a drop metastases is considered. Patients with tumors that are associated with familial conditions, such as neurofibromatosis or Von Hippel-Lindau syndrome, will require imaging to exclude the other disease-specific manifestations.

■ SURGICAL TREATMENT

Indications for Surgery

Surgery is indicated for one or more of the following reasons: to achieve neurological decompression, obtain a tissue diagnosis or for oncological resection. The advent of MRI may have led to an increase rate of detection of tumors.² The decision to operate needs to be weighed up with the natural history of the individual tumor. There is, however, limited literature on the natural history of these tumors. Ozawa showed that for intradural-extradural tumors, meningiomas were more likely to grow and eventually require resection than schwannomas.⁴⁹ The

Figs. 120.6A to C: MRI appearance of a dumbbell schwannoma.

Figs. 120.7A to C: MRI appearance of a filum terminale myxopapillary ependymoma.

decision of whether and when to operate needs to be tailored to the individual patient and tumor type. In asymptomatic patients, diagnostic ambiguity, development of symptoms, and tumor growth on imaging are factors that suggest surgical intervention. Otherwise, it is acceptable to follow an asymptomatic intradural tumor, especially when the radiologic features are consistent with a known tumor

pattern. Another consideration is that smaller tumors are easier to resect.⁴⁹

Establish Surgical Aims

Prior to surgery, all available information should be reviewed and studied. Although the diagnosis is not certain

Table 120.3: MRI features of intradural intramedullary tumors.

Features	Ependymoma	Astrocytoma	Hemangioblastoma
Incidence of intramedullary tumors	60%	30%	Up to 8%
Location	C > T > L	C>T (usually <4 segments)	C>T (dorsally located in >90% of cases)
T1 signal	Iso	Hypointense	Iso
T2 signal	Slightly hyper	Hyperintense	Hyper
Enhancement pattern	Most enhance homogeneously	Often enhance, usually heterogeneously	Usually enhance, may have enhancing mural nodule
Associated cyst/syrinx	More likely	Less likely	Often have a cyst, syrinx is uncommon
Demarcation	Clear margin in most	Poor demarcation in most	Clear margin in most
Hemorrhage	May have hemosiderin ring or hemorrhage “cap sign”	Rare	Flow voids, serpentine vessels
Other	Most central	More eccentric	Look for other manifestations of Von Hippel-Lindau

(MRI: Magnetic resonance imaging).

until pathological confirmation, the imaging will provide a high likelihood of the individual tumor type and specific surgical complexities associated with it. Options on surgical approach, extent of resection, degree of aggressiveness of surgery and contingency plans need to be considered. The surgeon should take into account both tumor and patient factors, present options to the patient, and consider the patient's wishes. Comprehensive discussions with the patient preoperatively are required to prepare the patient and give realistic expectations. From a symptom point of view, the main aim of surgery is to stabilize neurology. For intramedullary tumors, it is not uncommon for patients to experience worsening of neurological function postoperatively, at least transiently. It is useful to review imaging at rounds, tumor board meetings, with colleagues or neuro-radiologists. This may provide additional insights that are valuable in surgical planning.

Preoperative Considerations

Surgical Approach

The surgical approach is dictated by specific anatomy of tumor. For the majority of tumors, even if located ventrally, a standard posterior laminectomy or posterolateral approach will suffice; however, an anterior approach remains an option particularly in the subaxial cervical spine.⁵⁰ Spinal stability needs to be considered, and if wider exposures are required there may be a need for stabilization.

Anesthetic Considerations

The surgeon and anesthesiologist should discuss the important aspects of the surgery ahead of time. Neuroprotective measures, such as administration of dexamethasone and maintenance of normotension, are standard considerations but especially pertinent to tumors causing spinal cord compression or raised intrathecal pressure. If neurophysiological monitoring is to be used, the anesthetic may need to be tailored to accommodate this, e.g. by avoiding neuromuscular blockade. Cervical tumors may produce postoperative respiratory difficulties that may require intensive care unit.

Tumor Localization

Tumor localization can be a challenge, particularly in the thoracic spine. It is often beneficial to obtain plain radiographs for evaluation of anatomical anomalies, such as transitional or additional vertebrae; such findings potentially confuse intraoperative localization if not previously identified. These findings may be missed on an MRI. In some cases, radiolucent features that succor localization may be seen on a radiograph, such as tumor calcification or remodeling of surrounding bone. Radiological-guided skin marking can also assist; however, it is important to ensure that patient positioning during the localization mimics the operative position to reduce skin distortion.⁵¹ Navigation is used increasingly in spine surgery for instru-

mentation; however, the ability to merge soft tissue with bony imaging within the spine, as is done for brain tumors, to assist with tumor localization and guide resection is not yet available.⁵²

Equipment

The need for neurophysiological monitoring, image guidance, spinal instrumentation, intraoperative ultrasound and other useful adjuncts needs to be considered and organized preoperatively.

Neurophysiological is used routinely in some centers and has been shown to have a role in predicting postoperative deficit and recovery;^{7,53} however, it has not been proven to prevent deterioration.⁵⁴ Despite this, it is considered an extremely useful tool that provides real-time feedback during surgery.^{7,53,55} Monitoring options include evoked potentials—both sensory and motor that are useful for lesions around the spinal cord and free-running electromyography for lesions around nerve roots with or without stimulation. It is recommended that monitoring continue throughout the whole case, as late changes may occur following tumor resection; these may necessitate alternate measures such as duroplasty.⁵³

Intraoperative ultrasound is a useful adjunct providing real-time imaging of the lesion and its relation to the neural elements.^{56,57} It is especially useful for confirming adequacy of the surgical corridor.⁵⁸ We recommend its use following the laminectomy, prior to the durotomy.

Surgical Procedure

Following endotracheal intubation, insertion of arterial lines and urinary catheter, the patient is positioned prone in the military position. Prophylactic antibiotics and dexamethasone are administered. Neurophysiological monitoring is attached. Care is taken to ensure that the neck is gently flexed and the spine is straight and not rotated. The Mayfield skull clamp secures the head and neck in cervical and upper thoracic cases; however, we recommend it to use in all cases as it reduces pressure to the eyes and facial pressure sores, although it does not prevent ischemic optic neuropathy.⁵⁹ All pressure areas are protected and deep venous thrombosis prophylactic measures ensured. The surgeon encircles the table to recheck the aforementioned factors. The appropriate level is marked, and sterile prep and draping are performed in the usual manner. Local anesthetic is infiltrated and a midline incision is then

made. Subperiosteal dissection is performed to expose the appropriate laminae. Level reconfirmation is recommended prior to performing standard laminectomies. The intraoperative ultrasound is used to confirm the location of the tumor and that the laminectomy provides adequate exposure both in the rostral and caudal directions.⁵⁸ Once the exposure is adequate, care is taken to ensure adequate hemostasis from the bone edges and epidural veins. Irrigation is used to remove bone dust and debris. Bone wax is used on the laminectomy kerf and hemostatic agent, such as gelatin sponge, packed laterally at the bone dural interface. The microscope is brought in and the microinstruments made accessible. A midline durotomy is then made and the arachnoid opened allowing for CSF drainage. Hitching sutures are then used to retract the dura laterally and care taken to prevent blood run in, maintaining a bloodless intradural field.

Intramedullary Tumor Resection

Using the microscope, the spinal cord is inspected; the tumor may be obvious on the cord surface or an expanded cord may be noted. The overlying pial blood vessels are sometimes suffused. If necessary, the dentate ligament can be focally divided to allow for gentle rotation of the cord. The intraoperative ultrasound may be useful at this stage to delineate the tumor and assess where it is closest to the surface of the cord.

A myelotomy can be performed through one of four locations—dorsal midline, the dorsal root entry zone on either side or where the tumor presents itself to the surface. The most typical site for the majority of tumors is a dorsal midline myelotomy. Ventrally located tumors such as hemangioblastoma that present to the cord surface have been approached from anterior.⁶⁰ A ventral myelotomy is not recommended due to disruption of the anterior corticospinal and spinothalamic tracts.⁶¹ For ventral or eccentric tumors, a myelotomy through the dorsal root entry zone remains an option in select cases.⁶¹

Following myelotomy, the tumor is inspected with particular reference to its surgical plane. Resection technique is tailored to the tumor using standard microneurosurgical principles. The tumor is dissected from the cord and not the cord from the tumor. To avoid excessive manipulation of the cord, it is often advisable to debulk the tumor first. An ultrasonic aspirator is an invaluable tool for this. Alternatively, a side-cutting aspirator can be used as it offers the advantage of having a low profile with a side cutting port

providing superior visualization and it does not produce heat.⁶²

Ependymomas and hemangioblastomas are typically well circumscribed and have a good plane; this is less frequently the case with astrocytomas. If a poorly demarcated tumor is encountered, it may well be a diffusely infiltrating glioma, and the decision to biopsy alone should be strongly considered. Frozen section may be helpful, especially if it reveals a high-grade malignancy; however, the decision on the extent of resection depends mainly on the surgical circumstances and perceived safety of resection. Maintaining the tumor-pial plane and avoiding entry into the tumor are especially important for hemangioblastoma resection. These tumors are highly vascular and systematically cauterizing its blood supply circumferentially is required.

Following tumor resection, the tumor bed is irrigated and inspected to ensure hemostasis. It is advisable to minimize retention of hemostatic agents within the cord if possible. Standard watertight dural closure is then performed; however, if there are concerns of cord swelling or impairment of normal CSF flow around the cord an expansion duroplasty should be considered. A valsalva maneuver can be employed to exclude CSF leak from the dural closure. Fascial and skin closure should be performed in a watertight fashion as well.

The patient is typically nursed recumbent for 24–48 hours and then elevated as tolerated by low-pressure symptoms. The wound should be frequently checked for CSF leak. A postoperative MRI may be performed as a baseline and then should subsequently be performed to monitor for recurrence at increasing intervals.

Intradural Extramedullary Tumor Resection

The location of the dural attachment of meningioma is shown in Figure 120.8. The surgical approach is usually posterior⁶³ even for ventral tumors.⁶⁴ The location of the dural attachment should be identified and, if possible, dealt with first as this will reduce the tumor blood supply. There is considerable debate as to the extent of dural resection. Radiological studies have failed to predict dural invasion preoperatively.^{65–67} Some studies have concluded that a Simpson⁶⁸ grade 2 resection with coagulation of the dura is sufficient and the added risk of dural resection unnecessary.^{63,69,70} However, others have shown no recurrence in Simpson grade 1 resection and advocate this when feasible, particularly in younger patients.⁶⁷ The overriding principle in meningioma resection, as with any

Fig. 120.8: Location of dural attachment of spinal meningiomas.⁷⁰

other tumors, is to avoid pressure on the cord. The dentate ligament can be divided, which allows for gentle rotation of the cord to facilitate greater exposure of the tumor. Internal debulking of the tumor is often a necessary step to reduce its size and aid removal without cord manipulation. Extensive calcification is an independent risk factor for complications,⁷⁰ but careful use of the ultrasonic aspirator with specific attachments for calcified tumors may aid in debulking.

For nerve sheath tumors that require more extensive bony removal, segmental instrumentation may be required. Identifying the proximal and distal nerve fascicle is an important first step, and then the tumor can usually be dissected free from the normal fascicles. Neurofibromas typically have more involved fascicles than schwannomas,⁷¹ and schwannomas often have “onion skin” layers that can be gently dissected. Stimulation may be helpful in differentiating motor from sensory rootlets. Schwannomas typically arise from a sensory rootlet, and²⁰ in certain situations, especially in thoracic locations, sacrificing a rootlet may be necessary.

For tumors at the conus and cauda equina level, identification of the filum terminale will help to distinguish a nerve sheath tumor from a myxopapillary ependymoma. The filum typically is whiter than the nerve roots, it is surrounded by a squiggly vessel and intraoperative electrical stimulation will be negative.⁷² The filum should be divided cephalad first to avoid a retraction of the tumor into the conus.⁷² Spillage of tumor cells into the CSF should be minimized. Closure and completion of the operation are discussed above.

Complications of Surgery

Neurological Deficit

The most feared and devastating complication is that of a postoperative neurological deficit. In many cases, the cause remains allusive; however, the potential causes will be discussed with emphasis on complication avoidance.

Positioning is a particularly important part of the operation as it determines and facilitates the ease and safety of surgery. Patients with cord compression may be exquisitely sensitive to changes in position due to the resultant change in canal diameter. This may be assessed preoperatively when the patient is awake by testing the patient's range of motion to the point where symptoms appear. In patients with cervical tumors who have symptoms on minimal extension or the presence of L'Hermitte's sign, an awake fiber optic intubation should be strongly considered and extension avoided during positioning. Furthermore, the use of neurophysiological monitoring during positioning may be helpful. Care should be taken during the laminectomy to minimize pressure on the cord within a stenotic canal. The bone scalpel is an option for performing the laminectomy as it has been shown to reduce downward pressure.⁷³ The liberal use of magnification and microsurgical techniques are recommended during tumor resection. Respecting the tumor–pial interface and preserving pial vasculature is of paramount importance. In an unfortunate situation in which a patient awakes with an unexpected new neurological deficit, it is important to exclude reversible causes, such as a compressive hematoma or misplaced hardware. Urgent imaging is therefore recommended. In some cases, a deficit may be due to postoperative swelling but this is a diagnosis of exclusion.

Instability

Postoperative instability may occur in up to 10% of cases.⁷³ This is usually related to the extent of bony resection. In certain cases, where a facetectomy or wide exposure is required, particularly in the case of peripheral nerve sheath tumor consideration for segmental instrumentation should be given. There are increasing reports of minimally invasive spine techniques being employed for intradural tumor resection,^{74–77} including endoscopic techniques particularly in pediatrics.⁷⁸

CSF Leak

Despite watertight closure of the dura, CSF will invariably leak into the paraspinal region for a period of time.

Generally, this is not clinically apparent; however, complications may present themselves if there is persistent or cutaneous leak. Regular wound checks are performed to detect a cutaneous leak of CSF and if found should be addressed early to prevent infection. A contained pseudo-meningocele will generally regress without intervention but in rare situations a pseudomeningocele can cause compressive neuropathy.⁷⁹

Patients may present with low-pressure symptoms such as headache upon head elevation associated with nausea and vomiting. This is minimized with slow and gradual elevation of the patient after recumbency and returning to a supine position should symptoms emerge.⁸⁰ Patients with persistent symptoms, particularly if elderly, should have a CT brain scan to exclude intracranial pathology such as subdural collections or remote cerebellar hemorrhage, a recognized sequel of CSF leak.⁸¹

An identified leak can be confirmed to contain CSF using the laboratory test of beta 2 transferrin, which is unique to CSF and vitreous of the eye.⁸² Causative factors, such as raised CSF pressure or hydrocephalus, need to be excluded or treated. Other more common causes of wound drainage such as primary wound problems or infection can then be addressed. Revising the wound closure may be all that is required in association with resumption of recumbency. Cerebrospinal fluid diversion using a lumbar drain is often useful to facilitate wound healing; however, these are not without their own complications.⁸³ Other options include a blood patch⁸⁴ or the use of fibrin glue over the dura, although these are of limited benefit.

Pain

Patients may develop new pain or have worsening neuropathic pain postoperatively. In addition, patients will have expected postoperative wound pain. Individualized pain management by a pain team optimizing medical and other therapies is useful in minimizing this.

Outcomes

The best predictor of outcome is the patient's preoperative neurological status. However, tumor histology, grade, and extent of resection are also important predictors of outcome.^{8,85}

For meningiomas, a younger age of presentation has been associated with a more aggressive histology.⁸⁶ Myxopapillary ependymoma recurrence has been associated

with extent of resection.⁸⁷ The location of the tumor influences the extent of resection with conus tumors less likely amenable to gross total resection.^{18,87} Distant metastasis is rare but has been reported,⁸⁸ and tumor spillage into the CSF should therefore be minimized during resection.

For intramedullary tumors, gross total resection is much more likely in ependymomas and hemangioblastomas compared with astrocytomas.⁸⁵ Patients with incomplete astrocytoma resection need close follow-up with imaging, and radiotherapy should be considered for enlarging tumors.⁸ Higher-grade gliomas will require prompt neurooncology consultation for consideration of adjuvant treatment upfront. Patients with ependymoma recurrence should be considered for second resection.⁸⁵

CONCLUSION

Intradural tumors are rare and most are benign. They are distinguished by their location, with two thirds being extramedullary and one-third intramedullary. Surgery is indicated for symptomatic lesions, cases of diagnostic ambiguity, or radiological evidence of growth. Most lesions are surgically resectable except astrocytomas, which are often diffuse and poorly demarcated, and lesions of the conus where gross total resection may not be feasible.

KEY POINTS

- Intradural tumors are rare.
- Most tumors are benign.
- Two thirds are extramedullary and one third intramedullary in location.
- Surgery is the primary mode of treatment and indicated for lesions that are symptomatic, show radiological evidence of growth or where there is diagnostic ambiguity.
- Astrocytomas are often poorly demarcated and may be not amenable to complete resection.

INTRODUCTION

Spinal vascular malformations are uncommon pathologies, including both extra- and intradural lesions.¹ The clinical picture and evolution depend on the underlying pathophysiologic mechanism: hemorrhage, spinal cord ischemia secondary to either a phenomenon of spinal cord blood flow steal or to venous congestion or thrombosis, or mass effect.^{2,3} Extradural malformations, which are the most common ones and representing >80% of all lesions, include vertebral hemangiomas and intraspinal-extradural vascular malformations.⁴ The intradural lesions include intramedullary glomus arteriovenous malformations (AVMs), juvenile AVMs, spinal dural arteriovenous fistulas (SDAVFs), spinal cord (intradural perimedullary) arteriovenous fistulas (SCAVFs), and cavernous malformations (CMs).⁵⁻¹⁰

ANATOMY

The vascular network supplying the spinal cord is formed by vertebromedullary arteries, which originate from vertebral arteries in the cervical segment and from intercostal and lumbar arteries in the lower segments of the spine. Each vertebromedullary artery enters the spinal canal through a vertebral foramen together with a spinal nerve and divides into a vertebral branch and a medullary (or spinal) branch. This penetrates the outer dural layer and

is then divided into a dural artery and a radicular artery. The dural artery provides blood supply to the spinal and nerve root dura. Anterior and posterior radicular arteries, which originate by the bifurcation of the radicular artery, provide the vascularization of anterior and posterior nerve roots. Moreover, the anterior radicular artery passes above the ventral surface of the spinal cord, where it connects to the contralateral one in the midline and forms the anterior anastomotic artery, also named anterior spinal artery (ASA). Each posterior radicular artery on the posterolateral surface of the spinal cord is divided in an ascending and a descending branches, forming on both sides the posterolateral anastomotic vessels or posterior spinal arteries. The ASA and the two posterior spinal arteries are linked by a dense network of subpial anastomotic branches, forming the so-called perimedullary arteries network. Several perforating arterial branches, which are further distinguished in long branches supplying the grey matter and short ones supplying the white matter, originate from this vascular structure.¹¹⁻¹⁵

The blood supply to the mid-thoracic and inferior segments of the spinal cord (Th8-L2) and cauda equina is provided by the great anterior segmental medullary artery, also named with the eponym of Adamkiewicz artery. In 75% of people, this artery originates on the left side of the aorta between the T8 and L1 vertebral segments,^{16,17} and gives anastomotic branches to anterior and posterior spinal arteries.

A complex network of veins surrounding the spinal cord forms a venous coronal plexus as well as usually paired longitudinal veins. The radicular vein segmentally receives blood from this network, then pierces the dura in close proximity of the radicular axilla.¹⁸ A good correspondence between arterial anatomical distribution of arteries and venous anatomy can be found in children. Indeed, a larger anterior median vein and two paired dorsolateral veins are recognizable on the surfaces of spinal cord. Additionally, a posterior median longitudinal venous collector can also be present. Conversely, in adults the presence of anastomotic branches may vary, and the ectasia or tortuosity of existing vascular tracts makes the interpretation of anatomy complicated. Cadaveric anatomic observation revealed that functional valve-like structures may be present between the epidural draining system and the intradural venous complex in order to minimize the reflux of blood from the epidural space.¹⁹

Interestingly, it is remarkable that the above-described dural artery and the corresponding vein can give rise to an arteriovenous shunt within the dura, in close proximity to the origin of the spinal root.

CLASSIFICATION OF SPINAL ARTERIOVENOUS MALFORMATIONS

Over the years, different classifications of spinal AVMs have been proposed.²⁰⁻²³ These were based on intraoperative pathological appearance before the clinical introduction of spinal angiography²⁴ or on more detailed arterial and venous blood flow patterns demonstrated by spinal angiography.²⁵⁻²⁷

Classically, four AVM types are recognized: type I, dural arteriovenous fistulas (AVFs); type II, intramedullary glomus AVMs; type III, juvenile AVMs; and type IV, intradural, direct AV fistula. A type V malformation, consisting in an extradurally sited type III AVM, with peculiar pathoanatomical features, was subsequently added by Morgan and Morrill.²⁸

In 1987, Rosenblum et al. reviewed their own clinical data and proposed to differentiate spinal AVMs into malformations and fistulas, with either an intradural or dural location. In this up-to-date classification, intradural malformations included intramedullary glomus and juvenile AVMs as well as extramedullary AVFs. Dural malformations, specifically AVFs, were defined as having a retrograde drainage into perimedullary veins.²⁹

Spinal AVFs were found to have different and peculiar venous patterns, and such diversity was considered to be an important factor to evaluate in treatment decision-making process. In 1995 Borden et al. proposed a three-type classification of dural AVFs: type I, with an anterograde drainage into the epidural veins; type II, with a venous drainage into epidural (anterograde) and perimedullary (retrograde) drainage; and type III, with only a retrograde, i.e. perimedullary, venous drainage.³⁰ Two years later, in 1997 Bao and Ling also proposed some classification changes based on their experience in a series of patients.³¹ Their proposal for intradural AVFs defined three types of AVFs according to the number of feeding vessels and intensity of blood flow. In 1998, Kikuchi and Myasaka, considered three types of spinal vascular malformations: dural AVF, perimedullary AVF and intramedullary AVM.³² Perimedullary AVFs were further subcategorized into types 1-3 depending on the size of vascular pedicles.

In 2002 Rodesch et al. published their classification of spinal cord arteriovenous shunts: a distinction between AVMs and AVFs was presented, with the latter classified as either micro- or macrofistulas.³³ Furthermore, they identified (1) genetic hereditary lesions (macrofistulas and hereditary hemorrhagic telangiectasia), (2) genetic non-hereditary lesions, and (3) single lesions.

In the same year, Spetzler et al.⁸ proposed a new classification, as did Zozulya et al.⁹ in 2006.

Spetzler et al. identified a broad variety of vascular malformations, which were divided into three primary categories: neoplasms, aneurysms, and arteriovenous lesions. Neoplastic vascular lesions include CMs and hemangioblastomas, which both occur sporadically and familiarly; the second category includes the rare spinal aneurysms, which can arise from either radicular or main arteries, i.e. artery of Adamkiewicz; the third category is divided into AVMs and AVFs. In particular, AVFs are subdivided into extra- and intradural ones, with the latter categorized into ventral or dorsal lesions. Ventral AVFs can present small (type A), medium (type B) or large (type C) shunt; dorsal AVFs can have single (type A) or multiple (type B) feeders. The AVMs are divided into extradural-intradural and intradural malformations according to their neuroanatomical features. Intradural AVMs are further divided into intramedullary, intramedullary extramedullary and conus medullaris malformation. This is a newly classified juvenile-type AVM located in the conus medullaris and showing a better prognosis following surgical treatment. The Spetzler's classification proposal aimed at eliminating

the confusion inherent in previous classifications and, most importantly, at determining the appropriate surgical treatment.

Nonetheless, 4 years later Zozulya et al. designed a novel classification based on the anatomical characteristics and angiostructural and hemodynamic features. Zozulya argued that classification proposed by Spetzler was incomplete, not covering the entire spectrum of spinal malformation types. Zozulya's classification considered three parameters to define vascular malformations: localization (axial and lengthwise), vascular structure (feeding vessels, structural features, and venous drainage), and hemodynamic features. Axial localization is related to anatomical relationship between the lesion and the spinal cord, instead lengthwise depends on vertebral level. According to axial localization, malformations were divided in intramedullary, perimedullary, dural, epidural or combined. The structure of vascular malformations represents for importance the second parameter to be considered. According to this feature, AVM and AVF can have compact or diffuse arrangement of the nidus vessels. Taking into account hemodynamic data, the authors described three different types of blood flow (low, type A; moderate, type B; high, type C). To simplify the classification, the authors suggest to indicate first the axial localization of the malformation and its structural peculiarities, and then the other features (vertebral level, hemodynamic characteristic) as supplementary data. This new classification, in the authors' opinion, should be helpful to direct the decision process for best therapeutic strategy. Indeed the treatment—endovascular, microsurgical or combined—strictly depends on the type of malformation.

In the same year of Zozulya's paper, Kim and Spetzler published a new updated classification of spinal vascular malformation, based on anatomy and pathophysiology.¹⁰ First, the authors distinguished spinal arteriovenous lesions in arteriovenous fistulae and AVMs. These lesions were classified as extradural, extra-intradural or intradural. Intradural lesions were further divided into ventral or dorsal fistulae or into intramedullary lesions. The latter ones were defined as compact or diffuse. A new category, conus medullaris AVMs, was described as a new distinct entity.

In 2009 Da Costa et al. reported a 20-year experience on the surgical management of spinal vascular lesions, focusing on the correlation between classification and management.³⁴ He introduced a classification based on physiological and genetic data, according to which these lesions were considered as expression of a complex disease partly congenital and partly acquired.

Recently, Qureshi proposed a new classification scheme for spinal vascular malformations, based on angiographic data.³⁵ The most interesting aspect of his proposal is the statistical analysis performed to determine the inter-observer reliability of the new classification. He concluded that his new scheme proved to be sufficiently reliable even if used by less expert hands.

Such an increasing, and evolving, number and types of classification of spinal vascular malformations are testimony of the lack of a definitive and satisfactory patho-anatomical and physiological classification useful to help in deciding the best treatment modality in each single patient.

SUMMARY OF EPIDEMIOLOGICAL AND CLINICAL FEATURES

Regardless of the above described classifications, the epidemiological and clinical data related to the major spinal intradural vascular lesions are summarized.

Spinal vascular malformations are often underdiagnosed³⁶ and occur more frequently in male (male: female ratio of 2:1 to 4:1)³⁷ between 30 and 70 years of age. The thoracolumbar levels are the most frequently involved.^{2,38} The bleeding rate is related to the type of the vascular lesion. However, it should be highlighted that currently available epidemiological data are still partial and not completely reliable, because of lack of prospective studies on large cohort of patients.

Spinal Dural Arteriovenous Fistulas

Spinal dural arteriovenous fistula (SDAVF) is an arteriovenous abnormal communication that occurs within the dura of the spinal cord with the arterial supply usually arising from a dural branch of radicular artery.³⁹ An intradural vein drains the shunt directly into the pial veins of the cord leading to venous engorgement and venous hypertension, which in turn may lead to a venous hypertensive myelopathy. The chronic effects are believed to result in a myelopathic syndrome identical to that described by Foix and Alajouanine in 1926.⁴⁰ SDAVs represent the most frequent (70%) spinal vascular malformation and are believed to be an acquired condition resulting from thrombosis of the extradural venous plexus.^{36,41-43} They are usually tiny lesions, most commonly seen between Th5 and L3, and located adjacent to the intervertebral foramen.

The most common clinical presentation is related to myelopathy, with subacute or chronic onset of symptoms.⁴⁴ Hemorrhage is uncommon in SDAVs, which typically

appear in middle age causing a progressive worsening of neurological status. The clinical onset is characterized by pain, weakness, abnormal gait, urinary, and/or sphincteric disturbances.

Spinal Cord (Intradural or Perimedullary) Arteriovenous Fistulas

Spinal cord (intradural or perimedullary) arteriovenous fistulas (SCAVFs) consist of AVFs located on the surface of the spinal cord and fed directly by arteries supplying the cord, most frequently the ASA.⁴⁵ In dural location of the shunt, constant involvement of arteries supplying the spinal cord and lack of intervening nidus are angioarchitectural features that differentiate SCAVF from both SDAVF and SCAVM.^{46,47} They represent about 8–19% of all spinal intradural vascular malformation and are considered congenital lesions. Patients usually present in their second-to-fourth decade and the most common neurologic presentation is characterized by progressive asymmetrical radiculomedullary signs involving the lower extremities, related to the location in the lower thoracic, and lumbar region. Hemorrhage is also common.

Spinal Cord Arteriovenous Malformations and Subtypes

Spinal cord AVMs are believed to be congenital lesions. Most patients present in their second through fourth decade. The nidus of the AVM is located on or within the parenchyma of the spinal cord itself with arterial supply from anterior and posterior spinal artery or their branches. A feeding artery aneurysm is common due to the high flow nature of spinal AVMs. Intradural spinal AVMs comprise approximately 10–15% of all spinal AVMs.^{8–10,48} The incidence of subtypes is not totally clear because of the rarity of these lesions. The glomus subtype is characterized by a relatively compact nidus. The much less common juvenile subtype, also known as diffuse AVM, is characterized by an exceptional extension, with additional extramedullary and often extraspinal extension. The presence of AVM, especially type II and III (true AVMs), can determine stealing of blood from normal neural tissue leading to ischemia, venous hypertension, thrombosis and, most often, hemorrhage. This means that acute onset of symptoms is typical in case of hemorrhage; conversely, a progressive myelopathy could occur in case of blood steal and venous congestion (younger patients).⁴⁹ Spinal AVMs are most

common in the cervical and thoracolumbar region but may be found at any spinal level, including the filum terminale.

Spinal Cavernous Malformations

Unlike AVMs and AVFs, CMs are vascular lesions without high-flow AV shunts. Histology is similar, if not identical, to their counterparts in the brain. The CMs are intramedullary lesions and could affect the whole spinal cord.⁵⁰ Cauda equina and filum terminalis can also be involved.^{51,52} Typically, natural history of CMs is characterized by episodes of subclinical or not dramatic hemorrhage, alternating with long-time stability of the lesion. Patients most commonly present with discrete episodic neurologic dysfunction, with variable recovery between episodes. Monophasic acute or chronic deterioration of spinal cord function may also occur. The acute symptomatology is probably secondary to hemorrhage.

Spinal Aneurysms

Isolated spinal aneurysms are a very rare condition.⁵³ They are usually associated with other vascular lesion as AVM. Only few cases of isolated spinal aneurysms are reported and the treatment is usually endovascular.^{54,55} Patients may experience a spinal cord stroke or a subarachnoid hemorrhage. Aneurysms can occur within the arterial supply or venous outflow connections of the spinal cord. They are usually identified by their location, i.e. radicular artery aneurysm. There is not a clear predilection site at any specific segment of the spinal arteries. They are usually fusiforme and related to other general pathologies.⁵⁶ Differently from the intracranial aneurysm, spinal aneurysms are commonly expression of a systemic disease. Some cases of spinal aneurysm related to mycosis, vasculitis, hematologyphopietic or immune diseases have been described.^{56–58}

■ DIAGNOSIS

Diagnosis of spinal vascular malformations represented for many years the main challenge in the management of these conditions. The evolution of understanding and classification of these lesions is historically linked with their definition and presurgical recognition. Undoubtedly, the introduction of selective and ultrasensitive spinal arteriography in the 1960s, the subsequent widespread diffusion of magnetic resonance imaging (MRI) in the

1980s–1990s and, finally, the refinement and implementation of these radiological techniques allowed to improve the knowledge of anatomy and pathophysiology of spinal vascular lesions. Moreover, in the last decades, the large use of operative microscope [integrated in the last years with a device for intraoperative indocyanine green (ICG) videoangiography during neurosurgical procedures and the improvement of operative techniques allowed not only a postoperative good functional recovery but also a better knowledge of anatomy, pathophysiology and hemodynamic of spinal vascular lesions.⁵⁹

In cases of chronic or subacute onset of symptoms, the distribution of pain is not a reliable method to identify the site of the lesion. A clinical picture characterized by sensory involvement is generally related to a posterior localization; conversely, the anterior position of the lesion determines a upper or lower motor disorders, with or without pyramidal signs, that usually occur in the late stage of the disease.³⁷ The physical examination can orientate the diagnosis if two peculiar signs are detected: an arterial murmur (“the spinal bruit”)⁶⁰ that can be heard by placing a stethoscope over the spine is considered diagnostic for “true” AVMs (type II and III); the second sign to search is the presence of a cutaneous angioma on the back that could indicate the level of the malformation.²⁶

Neuroradiological diagnosis is the last and the most important step in pretreatment stage. The gold standard examination for the morphological definition of spinal vascular lesions still remains spinal angiography, except in cases of CMs.^{61,62} Angiography allows to exactly locate the lesion, depicting its extent, and investigating its angioarchitecture. Spinal angiography is indeed a dynamic examination that is able to show feeding pedicles and draining vessels, flow-related aneurysms and a nidus in case of AVMs. Stenosis of feeding and draining vessels should be also addressed for a correct treatment plan. The main limitations of spinal angiography are related to the difficulty in definition of precise arterial feeders in cases of extensive juvenile malformations with dilated arterialized veins involving multiple spinal levels. It is important to highlight that not every angiography exam can distinguish the precise location of the vascular lesion in respect to spinal cord (i.e. peri- or intramedullary localization).⁶³

Magnetic resonance imaging and computed tomographic (CT) scan angiography are of diagnostic value as well. In particular, MRI demonstrates dilated as well as thrombosed vessels, venous congestive myelopathy and intra- or perimedullary blood. Moreover, it allows a differential diagnosis between cavernomas, other vascular

lesions, intramedullary tumors and other spinal cord lesions such as axonal demyelination or infarction.⁶⁴ The MR typical features suggesting the presence of a fistula include: intramedullary hypointensity and flow voids on the cord surface (in T1 weighted sequences) prominent serpiginous intradural extramedullary flow voids along the dorsal aspect of the spinal cord, usually spanning more than three segments (in T2 weighted sequences, Figs. 121.1A and B, 121.2A, and 121.5B).

If angiography still plays an essential role in diagnosis of “true” AVMs (type II and III), last-generation MRI scan (Figs. 121.1C and D and 121.2B to D) and angio-CT scans (Fig. 121.1E) with multiplanar reconstruction have gained popularity in the recent years, as reliable, safe, and less invasive alternative in diagnosis of AVFs.^{65,66}

Currently, the armamentarium of neuroradiologists should be considered as an integration of different tools, including angiography, MRI, and CT. In the preoperative management of these complex pathologies, it is essential to acquire data from all imaging modalities, when applicable, in order to define the anatomy, the hemodynamic and the relationship with the spinal cord of these vascular lesions.

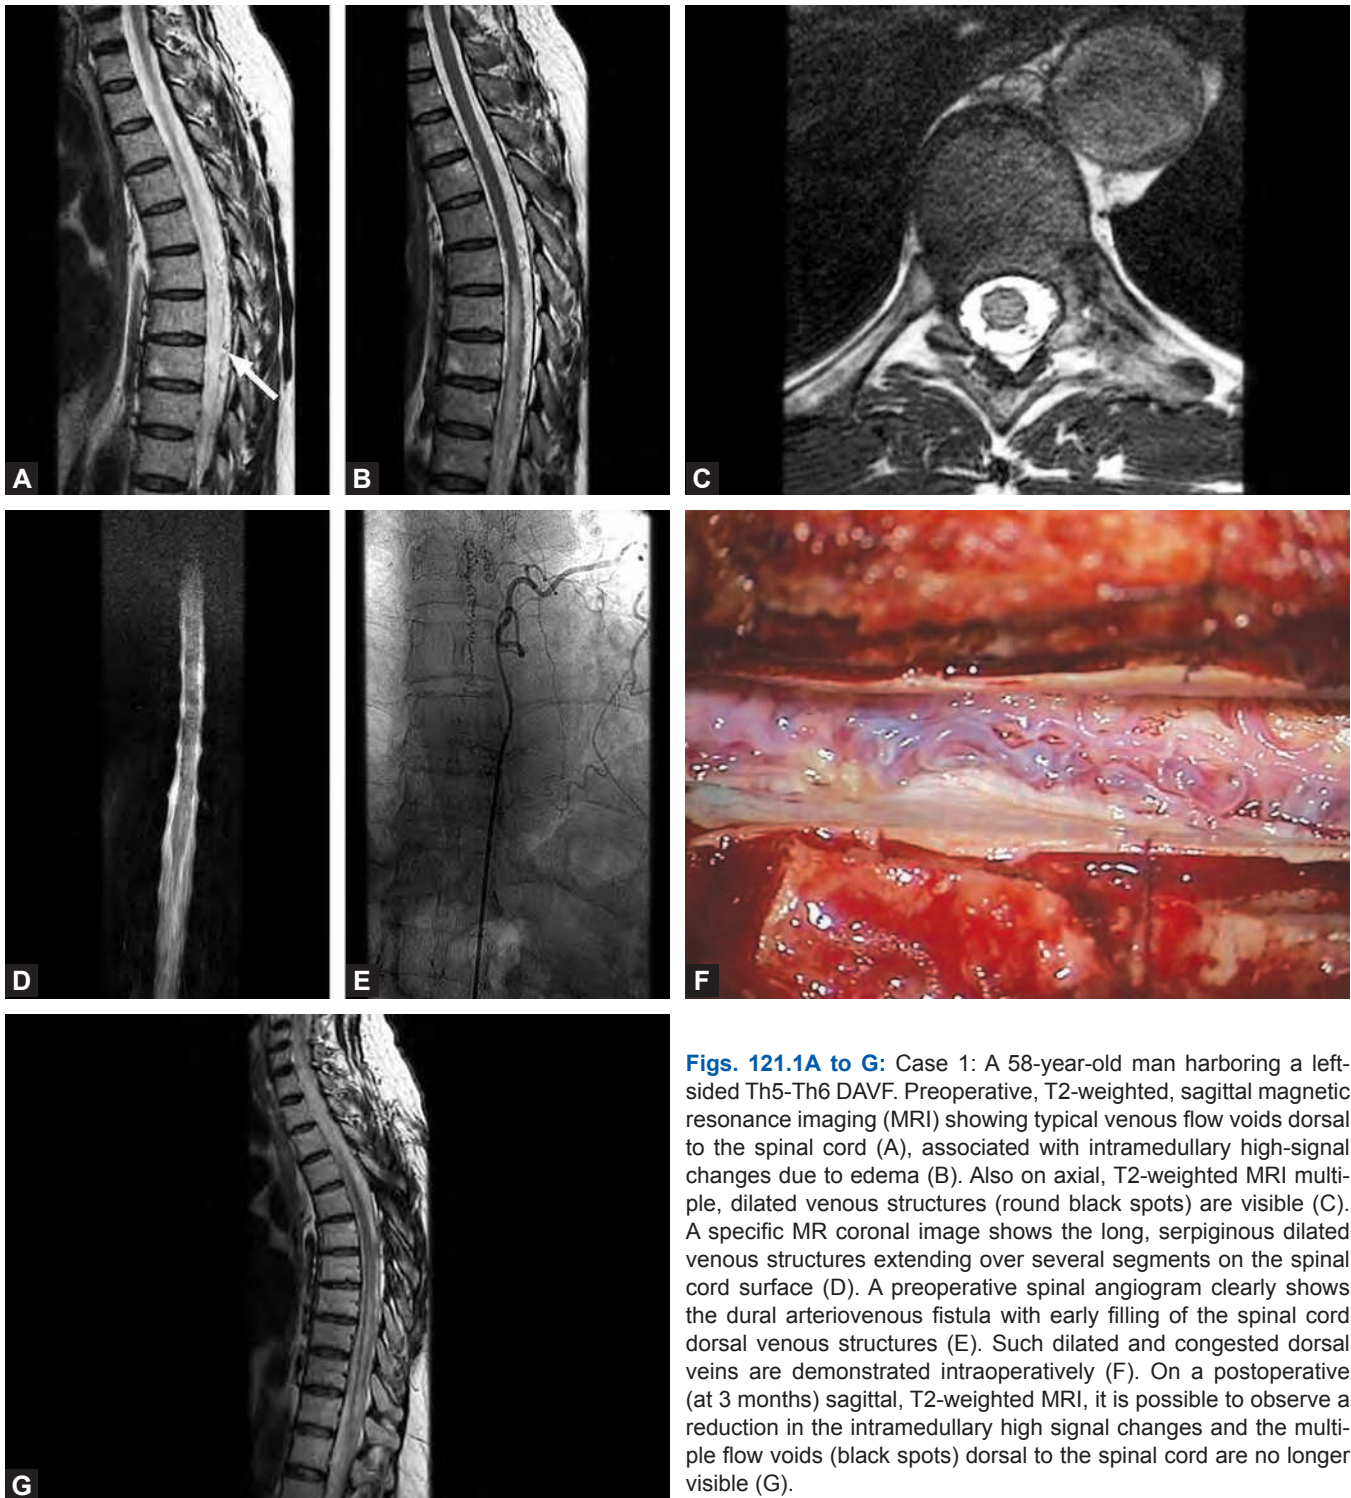

TREATMENT

Current opinions regarding the management of ruptured AVMs suggest a multimodal approach based on a combination of different therapies, including nonsurgical ones.^{67,68} In the contemporary “endovascular era,” surgery plays an increasingly limited but still crucial role. Indeed, surgical treatment of ruptured AVMs remains the only therapeutic modality in selected cases. Despite vascular neurosurgery has been recently deprived of the significant role typically retained in the past decades, as primary treatment modality, technological innovations like the use of intraoperative videoangiography^{69,70} and neuromonitoring⁷¹ have introduced a very useful support in the surgical management of vascular malformations.

Preoperative neurophysiologic evaluation by somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs) is useful to assess spinal cord function, according to the pattern of vascularization and location of the lesion.

Surgical Treatment

The goal of surgical treatment of intradural vascular malformations is the resection and/or the exclusion of the

Figs. 121.1A to G: Case 1: A 58-year-old man harboring a left-sided Th5-Th6 DAVF. Preoperative, T2-weighted, sagittal magnetic resonance imaging (MRI) showing typical venous flow voids dorsal to the spinal cord (A), associated with intramedullary high-signal changes due to edema (B). Also on axial, T2-weighted MRI multiple, dilated venous structures (round black spots) are visible (C). A specific MR coronal image shows the long, serpiginous dilated venous structures extending over several segments on the spinal cord surface (D). A preoperative spinal angiogram clearly shows the dural arteriovenous fistula with early filling of the spinal cord dorsal venous structures (E). Such dilated and congested dorsal veins are demonstrated intraoperatively (F). On a postoperative (at 3 months) sagittal, T2-weighted MRI, it is possible to observe a reduction in the intramedullary high signal changes and the multiple flow voids (black spots) dorsal to the spinal cord are no longer visible (G).

lesion from the normal vascular network, respecting the normal blood supply without damaging the spinal cord. Obviously, the surgical technique depends on the type of lesion.

Spinal Dural Arteriovenous Fistulas

The surgical treatment of SDAVFs still remains the gold standard procedure. Indeed, endovascular treatment does

have limitations due to the lack of long-term effectiveness of the occlusion. The aim of surgery is the interruption of communication between the arterialized vein piercing the dura and the congested coronal plexus. If this vessel is not recognizable, a correct interruption of the shunt is obtainable resecting the intradural nidus. Historically, the nidus of SDAVFs was wrongly identified in the large, tortuous, and congested pial venous plexus. This misunderstanding guided many surgeons' strategy to excise the coronal plexus by stripping off vein(s) from the spinal cord. This challenging procedure was always responsible for real disasters, without even being able to interrupt the abnormal communication in many cases.⁷²⁻⁷⁵ The dissected and removed congested plexus was instead the spinal cord normal venous drainage, with a retrograde flow. Therefore, the excision of such coronal plexus led to a further increase in venous congestion. Fortunately, a deeper knowledge of spinal cord's hemodynamics as well as of pathophysiology of SDAVFs allowed a change in anatomic target.

Surgery can be performed with a uni- or bilateral laminectomy extending one level above and one level below the nidus and the arterialized vein piercing the dura. After dural opening and exposing the spinal cord with dilated pial venous plexus, the fistulous point and feeder artery should be visualized (Fig. 121.1F). Such identification could be complex. The correct identification of the abnormal vessel could be obtained by accurate study of preoperative angiogram, remembering that the arterialized vein pierces the dura at level of posterior nerve root. However, the recent introduction of intraoperative ICG videoangiography allowed a faster and safer management of such surgical step. After individuation of the arterialized vessel, this is coagulated with bipolar forceps in a short segment (about 5 mm) near the dura. It is also described the placement of one or two vascular clips before coagulation. Controversy still exists about the need to complete the interruption by cutting the vessel.⁷⁶ Moreover, the ICG videoangiography helps to verify the correct and complete interruption of the shunt.^{69,70,77} Indeed, after coagulation or clipping of feeder vessel, the dilated venous plexus usually loses the usual "turgor" and it is possible to detect a change from reddish to bluish in the veins' color. The ICG videoangiography further confirms this observation, showing the restoration of normal blood flow direction and velocity. This will be slower and will have an opposite direction compared to preinterruption ICG videoangiography control.

Spinal Cord (Intradural) Arteriovenous Fistulas

As already mentioned for SDAVFs, the goal of surgical treatment of SCAVFs is the interruption of abnormal vessel causing the shunt between arterial and venous networks. This chapter discusses only intradural vascular malformation, and extramedullary fistulas will not be covered here. These lesions were classified by Merland in three different groups:⁴² small fistula located in the conus or filum terminale furnished by an abnormal ASA that appears long and thin (type I); a large fistula located anterolaterally or posterolaterally on the spinal cord surface with a lot of feeders from anterior or posterior spinal arteries (type II); a single giant fistula fed by abnormal ecstatic anterior and posterior spinal arteries (type III). Surgical treatment for type II lesion may be definitive, despite anterior or lateral location could make difficult the approach. A transvertebral route or a posterolateral approach with rotation of spinal cord could be performed with satisfactory results (Fig. 121.1G).^{27,78-80} For type I lesions with a lot of feeders, embolization may be performed before surgery in order to reduce vascular supply. Similarly a multimodal and multistep treatment, combining surgery and endovascular procedures, can be the best way to manage complex type III fistulas. In these cases, the goal of treatment is to halt the progression of myelopathy in order to improve the outcome.

Spinal Cord Arteriovenous Malformations and Subtypes

It does not exist the "best way" to manage spinal AVMs. The treatment is often a compromise between different therapeutic strategies. The decision for an adequate therapeutic planning should be individualized, taking into account the patient's health conditions, neurological status and, above all, the characteristics of the malformation. Many concerns are related to the timing of surgery in case of ruptured AVMs.^{47,48} The current trend is to delay the treatment in order to allow clot lysis and absorption of blood. However, surgical treatment of spinal AVMs is a real challenge for the neurosurgeon, who should apply every technological and human resource with the aim to minimize the risks and improve the outcome. As already discussed about SDAVFs, surgical exposure should be extended at least one level above and one level below the nidus (Figs. 121.2E and F). It is crucial a correct preoperative planning in order to accurately identify the exact

Figs. 121.2A to F: Case 2: A 66-year-old man suffering from spinal cord arteriovenous malformation. Preoperative, sagittal, T2-weighted magnetic resonance imaging showing many flow voids dorsal to the spinal cord; high signal changes are also seen inside the cord itself (A). A spinal angiogram shows, both in the arterial and in the venous phases, the arteriovenous malformation (B and C). A coronal, MR reconstruction clearly demonstrates the cervicothoracic vascular malformation (D). Intraoperative pictures (E and F) show a tangle of arteries and veins circumferentially located on the surface of the spinal cord, with some branches also entering the spinal cord's surface.

location of the nidus respect to vertebral bodies. The dura should be incised in the midline and a sharp dissection is preferable in order to avoid arachnoid injury. This can lead to laceration of adherent vessels under the dura. At the opening and exposure step, a very accurate hemostasis using bipolar forceps is recommended because the bleeding could stain surgical field, making difficult the recognition of the angioarchitecture of the nidus. After a good exposure, obtainable in case of intramedullary AVMs by a median sharp myelotomy, the interpretation of the anatomical features of AVMs is the most important phase before starting with coagulation and excision. Certainly, an accurate comparison with preoperative imaging is useful, but the application of

technologies could make the difference in complex cases. Intraoperative ultrasonography with the application of microprobes has a great usefulness to distinguish afferent from efferent branches. Additionally, hemodynamic data should be integrated by the application of intraoperative ICG videoangiography.⁸¹ This tool demonstrated a good effectiveness in not only depicting the anatomy of AVM nidus, but also giving real-time information about blood flow to the nidus vessels from it. When surgeon will have made all necessary reasoning about the AVM, the dissection may start. It is crucial to be sure to coagulate afferent branches in order to reduce first blood supply to the nidus and turgor of abnormal vessels. This reduces the risk of intraoperative bleeding and allows a better manipulation of

the lesion itself. Care should be taken in order to avoid the coagulation of an efferent vessel. This can lead to a dramatic increase of blood pressure into the nidus with a great risk of intraoperative rupture of AVM. In the dissection phase, bipolar forceps should be used electively on vessels, in order to avoid thermal damage on the spinal cord. Continuous irrigation is recommendable to maintain clean the surgical field and avoid sticking between forceps and vessels. For the largest feeders, ligatures or vascular clips could be applied. If ICG videoangiography is available, a last check after resection of the nidus is advisable. In cases of giant AVMs, multimodal treatment is advocated. In these cases, preoperative embolization can reduce the blood supply and may help the identification of feeders because particulate materials used for occlusion settle into afferent branches more than into efferent ones. Totally intramedullary AVMs should be considered for surgery only in selected cases. Ventral localization and great longitudinal extension are considered indication for repeated endovascular occlusion treatments. Giant juvenile type should be reasonably considered inoperable.

Spinal Cord Cavernous Malformations (Figs. 121.3A to G)

General considerations for indication to surgery in cases of spinal cord CM are the same already mentioned for AVMs. The ideal condition for surgery is a CM localized in the posterior half of the spinal cord, and accessible through the midline. Surgery for CM is similar to surgery for benign intramedullary spinal cord tumors (Figs. 121.3C and D). The goal of this surgery is the complete resection of the malformation because the residual nidus of angiomas tends to rehemorrhage, causing recurrent myelopathy. For this reason, an accurate inspection of the surgical bed of the malformation is advisable. Moreover, the presence of a hematoma in cases presenting with hemorrhage may complicate the procedure; therefore, a complete evacuation of the blood is mandatory before nidus resection.^{82,83} The potential usefulness of application of ICG videoangiography in spinal CM is controversial.⁸⁴ Probably, a large series of patients treated with this tool is required to draw meaningful conclusions about the pattern of fluorescence of such malformations.

Spinal Aneurysm

Because of their extreme rarity, isolated spinal aneurysms do not have a precise definition for management and

treatment. Usually, in unruptured cases related to systemic diseases, the first step consists in the management of the underlying pathology. Generally, surgical treatment of any spinal aneurysm should be performed only if the various types of inflammatory and noninflammatory vasculopathies are excluded as possible underlying etiology. Because many of the reported spinal aneurysms have a fusiform rather than saccular shape, standard surgical treatment may consist in trapping of the aneurysm or wrapping.⁵⁶

Endovascular Treatment

Goal and Indications

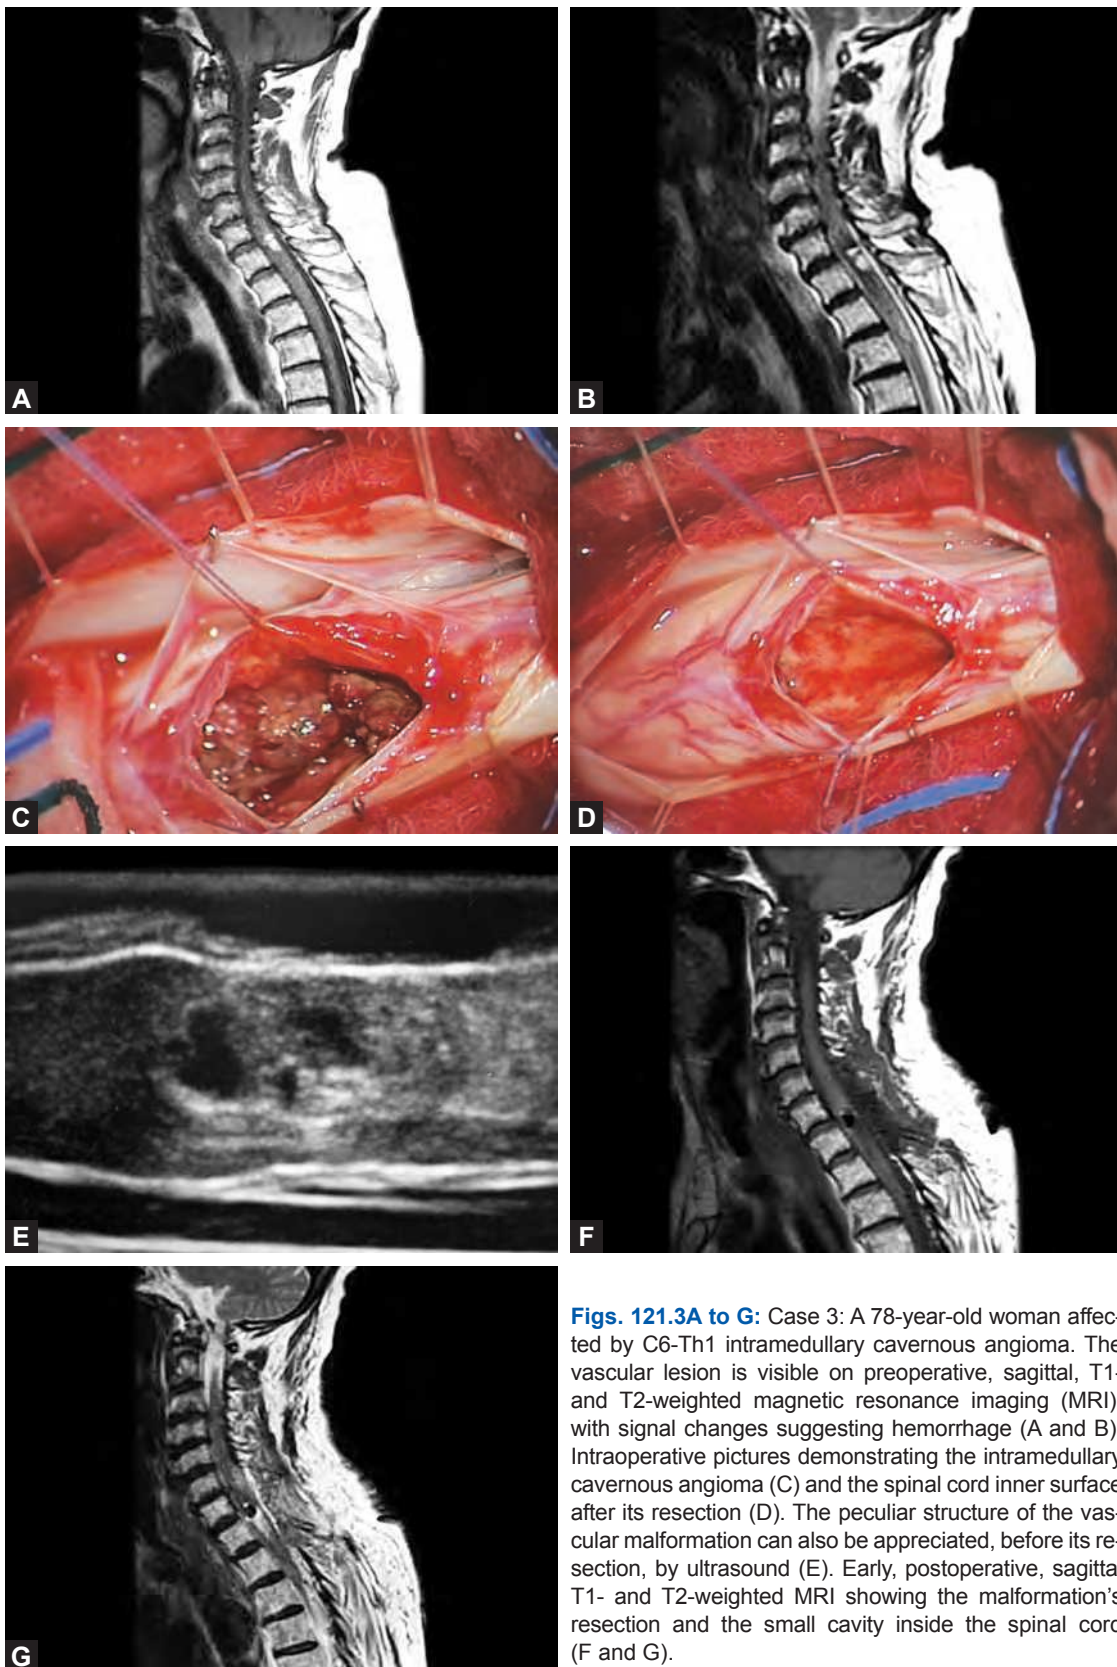

The goal of endovascular treatment of spinal vascular malformations is obliteration of the arteriovenous shunt with preservation of arterial supply and venous drainage of the spinal cord. It is crucial to occlude the AV shunt as distally as possible in order to reduce the risk of collateral recanalization. Symptomatic lesions should be treated as early as possible because the best predictor of clinical outcome is the pretreatment functional status.⁸⁵

Over the last decades, endovascular techniques are gaining appeal for the less invasiveness of the procedure over other therapeutic options; they allow diagnosis and treatment during the same session, even though in some cases multiple-step embolization is required.

The main indications for endovascular procedures are the following:

Symptomatic Spinal Vascular Lesions:

- *Arteriovenous fistulas (AVFs)*:
 - *Intradural dorsal AVFs (type I)*: when the dural artery supplying the shunt does not stem from a radiculomedullary branch. In this latter case, embolization may result in inadvertent occlusion of the ASA; in the latter condition, surgery is the best treatment option.^{8,10,61}
 - *Intradural ventral AVFs (type IV)*: endovascular management is well described for all three subtypes, even in case of giant lesions (subtype C of Spetzler classification), which display complex angioarchitecture with multipedicled feeders.^{61,86-87} Superselective catheterization allows visualization of flow-related aneurysms on feeders arising generally from ASA, which is necessary to identify accurately and to preserve proximally as well as distally (Figs. 121.5A to E).

Figs. 121.3A to G: Case 3: A 78-year-old woman affected by C6-Th1 intramedullary cavernous angioma. The vascular lesion is visible on preoperative, sagittal, T1- and T2-weighted magnetic resonance imaging (MRI), with signal changes suggesting hemorrhage (A and B). Intraoperative pictures demonstrating the intramedullary cavernous angioma (C) and the spinal cord inner surface after its resection (D). The peculiar structure of the vascular malformation can also be appreciated, before its resection, by ultrasound (E). Early, postoperative, sagittal T1- and T2-weighted MRI showing the malformation's resection and the small cavity inside the spinal cord (F and G).

Figs. 121.4A to H: (A) Preoperative catheter angiogram of a 32-year-old man presented with progressive cauda-conus medullaris syndrome secondary to a perimedullary arteriovenous malformation (AVM) at the conus medullaris (black arrow). This AVM is supplied by the anterior spinal artery (ASA), arising from a left-sided artery of Adamkiewicz (black arrowhead), branch of the thoracic aorta at the level of the 9th thoracic vertebra and drained by extrinsic perimedullary veins located over the anterior surface of the spinal cord (white arrows). (B and C) Note the UltraFlow flow-directed microcatheter (eV3, Paris, France) (yellow arrow) advanced progressively into the ASA, as far distally as possible. (D) Injection of glue, a Glubran 2-Lipiodol mixture (GEM, Viareggio, Italy) (red arrow), inside the arterial branch supplying the AVM, without reflux inside the ASA. (E) Note the glue (red arrow), projecting at the level of L2-L3 disc space. (F and G) Post-embolization spasm of ASA (black arrowheads). (H) Postembolization angiogram shows the ASA spasm resolved by a selective intra-arterial injection of papaverine (black arrowhead) (Ainhoa, France). No residual AVM is seen.

- *Arteriovenous malformations (AVMs):*
 - *Extradural-intradural AVMs (type III; juvenile; metameric):* these lesions are difficult to cure and their treatment is often palliative, the realistic goal being the reduction of vascular steal and vein engorgement, in order to ameliorate or stabilize the patient's neurological picture.^{8,10,61,86,87}
 - *Intradural-intramedullary AVMs (type II, glomus):* although complete embolization of such AVMs has been reported,⁶² as well as radical surgical resection,⁸⁸ even partial obliteration can improve patient's prognosis.⁶² Surgery alone is rarely the procedure of choice, especially when the nidus is diffuse and there are multiple feeders. However, combined endovascular and microsurgical treatment may offer the best chances for control of neurological decline.^{61,88}

Figs. 121.5A to E: A 45-year-old man presenting with progressive paraparesis secondary to intramedullary edema in the lower thoracic and lumbosacral spinal cord seen as hyperintensity in axial (A) and sagittal (B) T2-weighted magnetic resonance imaging. Flow voids (white arrows) surround the thoracic spinal cord and conus and are consistent with venous hypertension. Yellow line on sagittal image (B) indicates the level of the axial slice. (C) Catheter angiogram showing a dural arteriovenous fistula (DAVF) supplied by left third (black arrowhead) and fourth (yellow arrowhead) intercostal radiculomeningeal arteries forming a network (white arrows). The DAVF drains into a radicular vein connected with congested perimedullary veins (white arrows). (D and E) Postembolization angiograms after injection of both intercostal arteries show no residual fistula.

- *Conus medullaris AVMs:* for these very complex lesions, treatment is rarely purely endovascular, especially when dilated venous channels indicate surgical decompression of nervous structures to relieve neurological symptoms (Figs. 121.4A to H). Careful identification of ASA and branches of posterior spinal arteries separated from the malformation is crucial for avoiding postoperative neurological compromise.^{61,88}

In all cases, feasible selective catheterization of the feeding pedicles and familiarity of the treating physician with the use of liquid polymerizing agents are prerequisites for a successful embolization.

The contraindications of these procedures are the same as a routine procedure for intradural DAVFs: it is not suggested endovascular treatment when arterial feeders arise from arteries supplying the spinal cord nor when a CM is suspected.

Expert Suggestions/Comments

A thorough search of the vascular malformation must be conducted at all spinal levels as well as in the sacral and

cranial vasculature. As a matter of fact, AVMs and AVFs may often present with venous congestion many spinal levels away from the symptomatic level because of the longitudinal orientation and valveless nature of the spinal veins.⁷⁶

It is paramount to master the use of various liquid embolic agents (LEAs) in order to take advantage of the properties of each, especially viscosity, which helps in controlling their deposition.^{61,88}

Adjusted-dose intravenous heparin is used by the authors for the treatment of venous thrombosis when it extends to spinal cord draining veins, complication readily visible on angiograms.

Finally, when one is not certain about the consequences that an injection of LEA may have, the functional importance of the targeted branch, the stability of the microcatheter or the possible reflux of the embolic agent, it is better not to embolize at all than taking the chance.

Key Steps of the Procedure

The patient is under general anesthesia, in order to ensure comfort to the patient and reduce motion artifacts inducing apnea at the beginning of each image run. A percutaneous transfemoral modified Seldinger technique is used to introduce the catheter into the aorta. The sheath is introduced first, then a 6 French catheter is introduced through it and placed in the common femoral artery. After obtaining the initial aortogram to locate the lesion, all arterial pedicles that may give rise to a radiculomedullary artery are selectively catheterized by a guiding catheter and injected. Vertebral artery injection may also be needed when a high cervical vascular lesion is suspected. Then, superselective catheterization of the feeding vessels of the malformation is achieved. Flow-directed microcatheters best overcome vessels tortuosity and are less traumatic than the standard microcatheter/wire systems, thus reducing the risk of vessel perforation.⁸⁹ The aim of the superselective catheterization is placing the tip of the microcatheter in a wedge position as far distally as possible under simultaneous biplane fluoroscopic control, avoiding traumatic arterial vasospasm. Should vasospasm occur, 2 mg of Nimodipine is injected in situ, preventing the anesthesiologist for a possible drop of the systemic arterial pressure. After checking for microcatheter redundancy that may have developed during wire progression, embolic material is delivered to the nidus of the AVM or to the fistula site of the DAVF, as close to the vein as possible.

Adjustment of LEA viscosity aids in ensuring more precise embolization.^{61,88}

Intraoperative monitoring by SSEPs is a useful adjunct and MEPs prove very helpful in case of feeding vessels arising from ASA.^{8,10,61}

Avoidances/Hazards/Risks

The major risk of the endovascular treatment of spinal AVFs and AVMs is inadvertent occlusion of a radiculomedullary artery. This invariably results in spinal cord ischemia, which is critical when an isolated hairpin shaped radiculomedullary artery rather than a supplemental artery is occluded.

In some cases, venous thrombosis may extend from veins draining the vascular malformation to veins draining the spinal cord, with consequent myelopathy.

Salvage and Rescue

Adjusted-dose intravenous heparin is used by the authors for the treatment of venous thrombosis when it extends to spinal cord draining veins, complication readily visible on angiograms.

Postoperative Considerations

Femoral puncture is generally sealed by the Angio-seal device, to reduce the risk of hemorrhagic complications and promote ambulation in embolized patients undergoing intraoperative anticoagulation, unless arterial diameter is <4 mm. Otherwise, a compression of the puncture site is mandatory, followed by placement of a compressive dressing and immobilization of the leg for 24 hours in order to avoid bleeding from the puncture site. Lower limb evaluation and peripheral arterial pulses palpation are crucial in order to detect iatrogenic arterial dissection and stenosis due to hematoma at the puncture site. In some cases, postoperative red blood cells count, hemoglobin and hematocrit are warranted to disclose hemorrhagic complications following arterial puncture, which may not be readily visible due to possible diffusion in the retroperitoneum. Good hydration is advisable pre- and postoperatively in order to reduce drawbacks following contrast injection.

Postoperative neurological evaluation is mandatory to disclose iatrogenic myelopathy due to inadvertent embolization of functional branches or extension of venous thrombosis to veins draining normal spinal cord, which

can be managed by intravenous heparin. Follow-up consists of physical examination, spinal cord MRI and spinal angiography at 3 months postoperatively. If there is no residual AV shunt, a second spinal MRI is performed at 12-month interval. Further follow-up is based on annual physical examination, unless clinical relapse warrants a new spinal MRI.

COMPLICATIONS

Main complications occurring during the endovascular treatment of spinal cord vascular malformation are: iatrogenic arterial dissection during catheterization; hematoma at the puncture site, with possible femoral nerve compression; spinal cord ischemia due to closure of radiculomedullary arteries or its branches following inadvertent migration of embolic material or vasospasm secondary to vessel manipulation; myelopathy secondary to extension of venous thrombosis to the veins draining the spinal cord; and symptoms recurrence due to incomplete treatment of the vascular lesion.

OTHER TREATMENTS

Given the success in the treatment of vascular brain malformations, radiosurgery has also been proposed as an alternative and/or third-step treatment option for spinal vascular malformation. The main indication is in those malformations, which cannot be treated by surgical and/or endovascular techniques only and with a compatible size. The first experiences of stereotactic radiosurgery seem to have led to encouraging results;⁹⁰ however, there are no large series and extensive studies, which may allow an acceptable definition of reliability of these procedures on spinal vascular malformations.

KEY POINTS

- Intradural spinal vascular malformations include a large spectrum of different conditions. The classification and description of these pathologies are often challenging and require a complete knowledge of anatomical, hemodynamic and functional features of the lesions.
- To make a nosographic differentiation of spinal vascular malformations, four different groups should be distinguished: arteriovenous fistulas, arteriovenous malformations, CMs, and aneurysms.
- The onset of symptoms can be acute in the case of subarachnoid or intramedullary hemorrhage, due

to the rupture of an AVM, or chronic and progressive in the case of a worsening myelopathy related to venous stasis and/or mass effect. The diagnosis can be obtained interpreting data from different imaging techniques as digital subtraction angiography, angio-MR and angio-CT.

- The treatment decision-making process depends on the type of lesion. Surgery plays an important role in management of spinal dural arteriovenous fistulas and AVMs located on the posterior surface of the spine. Endovascular treatment may be considered as first-line or adjunctive treatment for complex malformations.
- A multimodal approach is suggested both for the management and treatment of such challenging pathologies.

INTRODUCTION

The rate of pyogenic disc infection and vertebral osteomyelitis (PDVO) is 2 per million people per year, comprising roughly 4% of all bone infections.^{1,2} Risk factors for spine infection include diabetes, immunodeficiency, ethanol abuse, intravenous drug abuse, infection at another site, steroid use, chronic renal failure, and malignancy.³ Prior to the modern era with its common use of antibiotics, the mortality rate was as high as 25%.⁴ Spinal epidural abscesses (SEAs) are exceedingly rare at an incidence of up to 2 per 10,000 hospital admissions.⁵ For SEA, the reported mortality was nearly 100% at the turn of the century, declining to 34% by mid-century, which eventually declined further to <15% by the end of the twentieth century.⁵ Initial reports of SEA identified a poor natural history, as seen in Dandy's reported series of 32 patients in 1926, with an 81% mortality.⁶

With today's widespread use of broad-spectrum antibiotics, most cases of spinal infection are treated conservatively with antibiotic therapy, with success rates reported as high as 95%.^{1,7,8} In the largest series to date of 915 patients, the most common infectious source was thought to be from furuncles and cutaneous abscesses. The most common presenting symptom was reported to be back pain that was present in 75% of patients.⁵ Interestingly, there is some recent evidence raising questions about the seasonality of postoperative spine infections. A review by

Gruskay et al.⁹ highlights evidence for a statistically significant increase in infection during the months when spring changes to summer, while a statistical decrease in infection is noted during the change from summer to fall. They speculate that this seasonal variation may be related to an increased volume of trauma requiring surgical care in summer.

PATHOGENESIS

Pyogenic discitis refers to a bacterial infection that has involved the intervertebral disc and end plates. The most common site of hematogenously acquired osteomyelitis is the vertebrae.¹⁰ The higher incidence in children is thought to be due to the robust blood supply to the nucleus that is seen in children, but not in adults. As one ages, the blood supply recedes from the nucleus, leaving the blood supply only reaching the outer fibers of the annulus, while the nucleus relies on passive diffusion for all other nutrients.

Spinal epidural abscess is an uncommon infectious disorder, first described in 1761 by a famous Italian surgeon named Morgagni.¹¹ The diagnosis was made postmortem. Of 45 SEAs, the predominant agent was *Staphylococcus aureus*, followed by coagulase-negative *Staphylococcus* species, and less commonly *Escherichia coli*. Gram-negative organisms are thought to be of increasing prevalence as a result of increasing spread from intravenous drug abuse.²

The primary mechanism of neurologic dysfunction is thought to be compressed by the infectious mass, followed by a local inflammatory response that can lead to thrombosis of compressed epidural and spinal veins.¹² To date, animal studies of *S. aureus* epidural injections in rabbits are the most thoroughly investigated models of SEA.^{12,13} After review, the authors conclude that mechanical compression of neural structures is the main mechanism for neurologic deficit in SEA. They suggest that neurological dysfunction is typically not due to compression of anterior or posterior spinal vessels, or to vessel thrombosis that was a prevalent belief. To the contrary, many investigators argue that SEA causes vascular damage by inflammation and thrombosis, resulting in cord hypoxia and further injury.¹⁴⁻¹⁷

In the cervical and thoracic spine, epidural abscess has been considered to be a neurosurgical emergency regardless of the presence or absence of neurologic deficit, given the risk of rapid, often irreversible, neurologic deterioration, and the risks of bacteremia and sepsis. Although there is an increasing trend to nonsurgical treatment, the primary treatment for SEA often is laminectomy and epidural drainage of the abscess.^{11,18-25}

CLINICAL RISK, PRESENTATION, RADIOGRAPHIC FEATURES, AND DIAGNOSIS

Clinical Risk Factors

Schuster et al., in a systematic review of literature to identify preoperative risk factors for infection in spinal surgery, found age, obesity, diabetes, malnutrition, a higher American Society of Anesthesiologists score, posterior surgical approach, and blood transfusions to be independent risk factors for infection.²⁶ Diabetes is among the most commonly cited risk factors for spinal infection.^{11,27-36}

Presentation

It is important for the clinician not to be dissuaded by the absence of fever or white count elevation, as they are often not present. Blood cultures are a routine adjunct to diagnosis, but keep in mind that they are only positive in approximately 50–72% of cases.³⁷ Erythrocyte Sedimentation Rate (ESR) and C-Reactive Protein (CRP) markers are also useful for following the clinical progression of the treated infection, with respect to the established baseline markers.³⁸ Sensitivity of ESR is reported as high as 98% in select studies.

Reihaus et al.,⁵ in a series of 915 patients with SEA, describe a progression of symptomatology: back pain leads to radicular irritation, which progresses to weakness from compression of the neural structures, and ultimately plegia. The most common age of presentation is usually >30.⁵ In 1948, Heusner and colleagues described the early stage is local inflammation and tenderness, followed by local signs of nerve irritation: Laseague's, Brudzinski, Kernig's, and Lhermitte's signs. Back pain was reported quite commonly in several large patient series. In the literature, the prevalence of radiculopathic features ranges from 12% to 47%.^{28,30} Roughly one quarter of patients present to the emergency setting with incontinence and paraplegia. Rectal tone, volition, and strength are important to document; as many as 38% of patients have urinary incontinence on presentation.^{11,33,39}

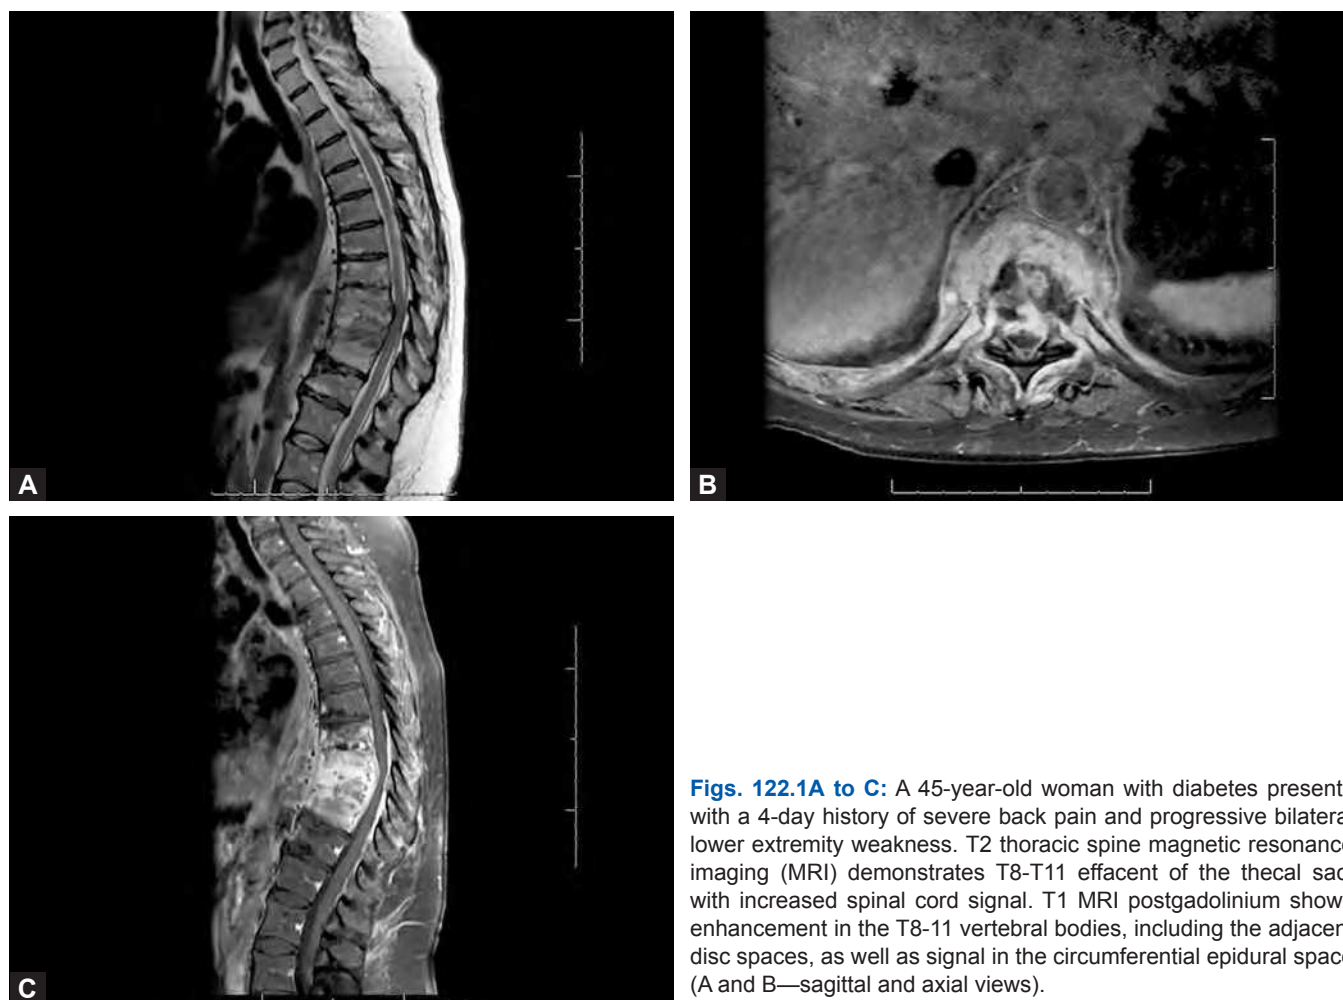

Magnetic resonance imaging (MRI) often with gadolinium contrast is the standard of care, and is sensitive even at the earliest stages.^{5,39-42} In a series of 20 consecutive patients with SEA, MRI demonstrated a heterogeneous collection in the epidural space, with a thick, peripherally enhancing collection of pus associated with local engorgement of the epidural venous plexus⁴² (Figs. 122.1A to C). spinal intramedullary^{43,44} and subdural abscesses are exceedingly rare.⁴⁵⁻⁴⁹ Lastly, computed tomography (CT)-guided biopsy is a helpful nonoperative diagnostic measure in up to 68% of cases, and this percentage is slightly higher when the cultures are taken intraoperatively.³⁷

TREATMENT

The indications for surgery for PDVO are neurologic compromise, mechanical instability, intractable pain, failure of antibiotic therapy, and the need to achieve a definitive diagnosis. In some cases, a SEA itself is indication enough for surgical treatment.⁵⁰ A SEA in the absence of discitis or osteomyelitis is usually treated with laminectomy without instrumentation and fusion. When the infection is severe, the postoperative placement of drains in the epidural space may be used for monitoring and continued drainage of pyogenic collections.

Instrumentation in the Setting of Infection

Despite the concern for bacterial colonization of foreign body implants, instrumentation in the setting of infection has been shown to be safe and beneficial to patients.⁵¹⁻⁵⁶

Figs. 122.1A to C: A 45-year-old woman with diabetes presents with a 4-day history of severe back pain and progressive bilateral lower extremity weakness. T2 thoracic spine magnetic resonance imaging (MRI) demonstrates T8-T11 effacement of the thecal sac, with increased spinal cord signal. T1 MRI postgadolinium shows enhancement in the T8-11 vertebral bodies, including the adjacent disc spaces, as well as signal in the circumferential epidural space (A and B—sagittal and axial views).

Lee et al.⁵⁷ in a retrospective review of >100 patients with pyogenic spine infections found a total of 30 patients requiring instrumentation. They concluded that the practice was effective for debridement of infection without recurrence. Moreover, postoperative stability was demonstrated with an effective fusion in 29 patients. Rayes et al.³ treated 47 patients with instrumentation and radical debridement for the indication of failure of response to antibiotic therapy and mechanical instability in the setting of spinal infection. The majority of these patients underwent anterior approach for the simultaneous decompression of the spinal canal and debridement of an infectious intervertebral process. All patients had improvement in American Spinal Injury Association (ASIA) grade at the time of discharge. Two patients developed recurrent infection and only one of those two patients required removal of instrumentation.

Cage Placement

Kyphosis after anterior debridement for vertebral osteomyelitis is a concern. Typically, many spinal surgeons use autograft or allograft tricortical iliac crest, less commonly employing fibular, femoral or rib strut grafts to provide structural support in the defect created by ventral debridement.⁵⁸ Posterior spinal instrumentation is often then provided as a second-staged procedure to facilitate stability and fusion.⁵⁹⁻⁶³ There is a growing body of literature to support the safe usage of titanium cage placement for anterior column support in the setting of instability with superimposed infection. Rosner et al. reported the results of a retrospective series of 21 patients, all of whom underwent anterior corpectomy and titanium mesh cage placement supplemented with allograft and demineralized bone matrix, followed by posterior instrumentation and fusion. Typically,

the posterior instrumentation spanned one to two levels above and below the site of corpectomy. An average of 13° of sagittal alignment was restored. Titanium was used by the author with the thinking that it may be less prone to colonization than bone or polymethylmethacrylate, given the decreased porosity of titanium. Hee et al.⁶² treated seven patients with titanium mesh cages packed with autograft followed by immediate posterior instrumentation, with excellent results, and without recurrent infection.

Anterior versus Anterior/Posterior Two-stage Approach for PVDO

To date, there are no prospective studies comparing anterior, posterior or combined approaches for the treatment of PDVO. Many spinal surgeons have felt that anterior or lateral approach to the treatment of anterior column pathologies such as pyogenic vertebral osteomyelitis and osteodiscitis is adequate. Addition of the posterior approach is justified by the belief that there is no direct contamination of the operative field by infection, although this theory has not been thoroughly investigated.

Still, there are many spine centers that feel that posterior spinal instrumentation is necessary to provide additional support. One counter-argument is that the surgeon should take all precautions to shorten the interval of malnutrition caused by spine infection and provide the most conservative surgical correction possible. The second-staged posterior approach may have an increased infection risk and prolong the malnourished state, putting the patient at increased risk for wound breakdown.⁶⁴ Dimar et al.⁵⁹ report good results with a delayed period prior to the second-staged posterior instrumentation by allowing for critical optimization of cardiac and respiratory status.

Single-stage Combined Anterior/Posterior Approach

Sharan and Przybylski reported a series of 17 patients treated for PDVO and discitis with a single-staged anterior debridement with iliac crest graft placement followed by posterior instrumentation and fusion.⁶⁵ Fountain published a series of 17 patients who were treated in a single-staged, combined anterior debridement with bone graft placement followed by posterior instrumentation and Harrington rod placement. He found a return to ambulation in all patients by 14 days and only one postoperative

recurrent infection and one hardware failure by 6-month follow-up.⁶⁶ Redfern et al.⁶⁷ utilized anterior debridement and posterior rod placement. They reported adequate postoperative pain relief and no recurrent infections on follow-up. Furthermore, Graziano and Sidhu⁶¹ achieved successful incorporation of the strut graft in all seven patients treated with combined anterior corpectomy and posterior instrumentation.

POSTOPERATIVE INFECTIONS

Postoperative wound infections can be classified as early or late, with 1 month being the cutoff point. An extensive review of >15,000 instrumented fusions found a postoperative infection risk of 8.5% and 12.2% in revision surgeries.⁶⁸ The average time for presentation was found to be 2 weeks. The most common pathogen responsible for spine infections is *S. aureus*, followed by *S. epidermidis*, *Propionibacterium acnes*, and *Corynebacterium*. The most common symptom is almost always severe pain, with the most common exam finding being wound drainage.

The Scoliosis Research Society in a 5-year database of spinal procedures calculated a surgical site infection rate of 2.1%.⁶⁹ It further stratified patients based on primary diagnosis, and found rates as high as 4% for patients with kyphosis. The significance of kyphosis may lie in the extent of surgery, in which deformity corrective measures for kyphosis carry longer operative times, increased estimated blood loss (EBL), and more involved spinal procedures. Significant risk factors for infection include the use of instrumentation, fusion, and revision surgery. When comparing open surgery versus minimally invasive approaches for both discectomies and transforaminal interbody fusions, the minimally invasive cohort carried a lower infection rate.⁶⁹ This is thought to be related to the fact that minimally invasive spine procedures often have smaller incisions and confer less tissue devascularization and damage. In the hands of the experienced surgeon, the surgical times would also be equivalent. One bias of these studies is that the majority of these studies are produced by proponents of minimally invasive spine surgery.

Olsen et al., in a retrospective review of patients undergoing laminectomy or fusion, found a surgical site infection rate of 2.8% over a 5-year period. Also, independent risk factors for infection were found to be posterior approach, tumor resection, postoperative incontinence, and morbid obesity.

Figs. 122.2A to D: A 30-year-old man with a history of intravenous drug use, and recent 2-day history of fevers presents with bilateral leg pain and urinary incontinence. Initial computed tomography scan shows erosive end plate changes at L4-L5 and L5-S1(A). L4-L5 and L5-S1 osteodiscitis with a circumferential dorsal epidural abscess on MR T2 and T1 post-gad imaging is seen (B and C). Circumferential epidural abscess was debrided, as well as in the interbody of L4-5 and L5-S1. Given the concern for mechanical instability noted intraoperatively, L4, L5, and S1 pedicle screws were placed [ap, radiograph, lumbar spine (D)].

Evidence for Removal of Hardware in Surgical Site Infections

The concern for foreign bodies in the setting of infection is its resistance to antibiotic therapy. One method of resistance to antibiotic therapy proposed is the formation of a glycocalyx biofilm layer over implants that form a shield resistant to antibiotic penetration.⁷⁰ Postoperative wound infections have a definition that varies from study to study. Wound drainage, radiographic findings, fever, and abnormal laboratory values all contribute to the suspicion of wound infection. Surgical treatment often involves, at minimum, debridement of nonviable

tissues and bone graft with placement of subfascial (Figs. 122.2A to D) and/or epifascial drains to monitor and drain wound collections. Intuitively, a solid fusion demonstrated by CT imaging in the setting of postoperative infection may make removal of posterior instrumentation an easy decision. Some clinicians argue for the removal of instrumentation in all cases of postoperative infection.⁷¹⁻⁷³ Sonntag et al.⁷⁴ argued that the instrumentation can be left in place to promote fusion, and demonstrated that this was safe practice in combination with antibiotic-fluid suction/irrigation systems placed after operative debridement of nonviable tissues, including infected bone graft (Figs. 122.3A to C).

Figs. 122.3A to C: A 56-year-old man with a C5 compression fracture with resulting kyphotic deformity fracture (A). Magnetic resonance imaging demonstrating cord signal edema from compression (B). Restoration of lordosis is achieved after C5 corpectomy, placement of tricortical iliac strut autograft, followed by short segmental posterior cervical decompression and fusion (C).

CONCLUSION

Definitive operative recommendations for PDVO and SEA are unavailable, given the lack of randomized controlled trials as well as the absence of prospective data. Also, the absence of a standardized methodology for characterizing spinal infections makes comparison of various studies challenging. Moreover, the definition of surgical site infection varies across the literature.

There is, however, strong evidence supporting surgical debridement of PVDO and SEA, as well as anterior column

reconstruction with bone graft or cage placement when there is substantial anterior bone and disc destruction and resultant instability, deformity, or a large anterior abscess. Posterior instrumentation is commonly performed for definitive stabilization after corpectomy or discectomy, though there is little evidence either way for this practice or for its timing. Most of the evidence gathered above does not support the claim that instrumentation in the setting of infection provides a risk for recurrent infection at 1–2 years follow-up.

INTRODUCTION

Spinal tuberculosis (TB) accounts for >50% of skeletal TB and is caused by the organism *Mycobacterium tuberculosis*.¹ The predilection of the microbe to affect the vertebral column is next only to the lungs and can be correlated to the high vascularity of the vertebral marrow. Spinal disease is most frequently located in the lower thoracic and thoracolumbar junction (50–70%).² Thoracic disease is more common in children and adolescents, whereas lumbar disease is found commonly in adults. The proximity of the cisterna chyli and the lungs, and the thoracolumbar junction being a transitional region between the stable thoracic spine and mobile lumbar spine makes this region favorable for bacterial lodging. Most cases of bone and joint TB are isolated to one area, but multifocal disease has also been described in up to 16% of patients.

The advent of chemotherapy has significantly improved the outcome of patients with TB. If initiated early, most complications of spinal TB such as neurological complications and deformity can be avoided by adequate chemotherapy. It is essential to understand that spinal TB is predominantly a medical disease, and surgery is indicated only in select situations.

PATHOGENESIS

Tuberculosis is caused by a bacillus of the *M. tuberculosis* complex. The most common of the group, *M. tuberculosis*,

grows slowly and stains acid fast because of a highly lipid and peptidoglycan-rich cell wall. It is a slow-growing aerobic organism with a growth-doubling time of about 20 hours in conditions favorable to the bacillus. In unfavorable conditions, it can grow only intermittently or remain dormant for a prolonged period.

Vertebral infection by the bacillus results from hematogenous dissemination from a primary focus, and associated active focus can be identified in only <10%. The primary focus may be active or quiescent, apparent or latent, and are usually in the lungs, lymph glands of the mediastinum, mesentery or cervical region, kidney or other viscera. Spread occurs to the vertebra through the blood stream along the arterial system. Alternatively, tuberculous bacilli may travel from the lung to the spine through the Batson's paravertebral venous plexus or by lymphatic drainage from the para-aortic lymph nodes.

Microscopic Features

Following the infection in the vertebral marrow, the initial inflammatory response is characterized by accumulation of polymorphonuclear cells, which are slowly replaced by macrophages and monocytes. The tubercle bacilli are phagocytosed and their lipid is dispersed throughout the cytoplasm of macrophages, transforming the macrophages into *epithelioid cells*. Epithelioid cells are characteristic of the tuberculous reaction. These are large, pale cells with

Fig. 123.1: Sagittal and axial magnetic resonance imaging demonstrate paradiscal type of lumbar tuberculosis with damage to the vertebral endplates and extension of infection into the vertebral bodies.

a large vesicular nucleus and abundant cytoplasm. Their phagocytic capacity is subdued and they become more secretory in nature. Another characteristic feature of tuberculous lesion is the presence of *Langerhans giant cells*, which are formed by the coalescence of a number of epithelioid cells and whose presence on pathological analyses may be helpful from a diagnostic point of view. Cellular immunity is mediated through lymphocytes, which form a ring around the peripheral part of the lesion and attempt to control the proliferation of the bacilli. This typical lesion of TB formed by the reactive cells of the reticuloendothelial tissues (the macrophages, epithelioid cells, Langerhans giant cells, lymphocytes, and inflammatory exudate) constitutes the *tubercle*. With progressive destruction, caseation occurs in the center of the tubercle due to coagulation necrosis. Presence of caseation necrosis is a diagnostic feature of TB. Adjacent tubercles then coalesce to form a large abscess filled with caseous material containing serum, leukocytes, caseous material, bone debris, and tubercle bacilli and lined by thin reactive capsule. Since it is a chronic infection, the acute features of inflammation like warmth and redness are absent and hence this abscess is termed as the *cold abscess*.

Macroscopic Features

The *Mycobacterium bacilli* reach the vertebra either through the vascular or lymphatic system and lodge in the subchondral marrow on either side of the disc due to the specific arterial anatomy of the paradiscal region. This is

the most common pattern of tubercular spinal infection called the “paradiscal” type (Fig. 123.1). The other types of TB are the “centrum” type (predominant vertebral body destruction), posterior type (predominant involvement of posterior elements) (Figs. 123.2A to C), and the nonosseous type (where bony destruction is less with extensive abscess formation). In the classic “paradiscal” type, the intervertebral disc is not involved primarily because it is an avascular structure. But progressive destruction of the vertebral end plates on both sides of the disc affects the nutrition of the disc, leading to collapse of the disc space. In the early stages, there is marked increase in the vascularity of the bone and hence severe osteoporosis ensues. Due to progressive destruction by the tuberculous bacilli and osteoporosis, there is osteolysis leading to compression, collapse, and deformation of the bones. Necrosis also takes place due to ischemia secondary to arterial occlusion. Vertebral body collapse leads to local kyphosis and retropulsed bony fragments can compress the spinal cord. In children, extensive involvement with complete destruction of many adjacent vertebral bodies may be seen.

Due to the chronic inflammatory response and the secretory nature of the epithelioid cells, extensive abscess formation is typical of TB, and spreading abscess formation in the epidural, prevertebral, and paravertebral regions is common. Extension of abscess into the epidural space can result in neurological symptoms and signs (Fig. 123.3).

CLINICAL FEATURES

Epidemiology

Spinal TB is common in the developing parts of the world among the lower socioeconomic strata. Crowding, lack of sanitation, reduced access to health care, and poor education are the reasons for the higher incidence in these regions. In developed nations, immunosuppression due to HIV, old age, and cancer chemotherapy has resulted in an increase in the incidence of TB of late. While spinal TB is common during the first three decades of life in developing nations, it affects the adults and elderly in the developed nations.

Systemic Involvement

It is important for the treating physician to understand that TB is a systemic disease and infection of multiple organs can coexist. An active concomitant primary tubercular infection elsewhere in the lungs, lymph nodes,

Figs. 123.2A to C: Posterior element tuberculosis. Tuberculosis of the spinous process of the L1 vertebra (A). Another patient with tuberculosis of the lumbar facet joint leading to anterior subluxation (B and C).

Fig. 123.3: Posterior epidural abscess of the thoracic spine causing cord compression. This is the only indication for an isolated laminectomy in a patient with Pott's spine.

intestines, ovaries, kidneys should be looked for. In spinal TB, multiple segments of the spine can be afflicted at the same time (Fig. 123.4). Though the presenting symptoms

and signs are usually due to one particular lesion, magnetic resonance imaging (MRI) of the whole spine often identifies multiple noncontiguous lesions in many patients. The incidence of such multifocal spinal TB varies from 1.1% to 71% depending on the type of investigation used to evaluate the spine.³ The reported incidence in centers that do not perform routine, whole-spine MRI is 1.1–10% using a combination of regional radiography, computed tomography (CT) and MRI, and 16% using 99 mTc-MDP bone scan and 71.4% when whole-spine MRI was undertaken.³ The lesions can be either in continuity or with skipped single or multiple uninvolved segments.

Pain in Spinal TB

Unlike pyogenic spondylitis, tuberculous lesions have a much more insidious onset and the clinical symptoms often develop over a period of 1–2 months. Back pain localized to the affected site and aggravated with spinal movements is the usual presenting feature. The back pain in TB can be attributed to chronic inflammation, segmental instability, distension due to abscess and pressure on

Fig. 123.4: Sagittal whole-spine magnetic resonance imaging demonstrates multilevel spondylodiscitis in the cervical, upper thoracic, and lumbar regions (arrows). The presenting symptoms were due to the lesion at the thoracic region.

neighboring structures. With development of instability, the pain changes in character and becomes quite severe. Patients may need to support their trunk by placing their hands on the couch while sitting (*tripod sign*) or hold the neck by their hands when the cervical spine is affected (Fig. 123.5). Rest pain at the affected region and sudden exacerbations (night cries) during sleep due to lack of protective muscle spasm are also common.

Radicular pain is an uncommon feature and if present, indicates compression on the nerve roots due to abscess or free bone fragments. Sometimes radicular pain along the thoracic nerve roots may be referred to the abdomen leading to misinterpretations as cholecystitis, pancreatitis, appendicitis, and renal diseases.

Constitutional symptoms of malaise, loss of appetite and weight, evening rise of temperature, and night sweats are also common but are more typical of pulmonary TB. These constitutional symptoms are observed in <40% of cases of spinal involvement and are more common in patients with associated malnutrition.⁴ Extensive disease can be present with minimal systemic disturbances in patients who have good immunity and nutritional status (Fig. 123.6).

Fig. 123.5: Cervical instability in a child due to upper cervical tubercular destruction. The child needs to support his neck to reduce instability pain.

Cold Abscess

A paravertebral cold abscess is a diagnostic feature of spinal TB and is observed in at least of 50% cases of spinal TB.⁵ It may be clinically evident, either in the paraspinous area or may tract distally depending on the region of involvement. The abscesses initially collect within the infective focus and may track along the perineural, perivascular, intermuscular, subpleural, subperitoneal, and natural areolar tissue spaces to present remotely away from the vertebral lesion (Table 123.1). Depending on the location, the abscess may collect either in the deeper planes or present superficially.

The common presentation includes the paravertebral abscesses in the thoracic spine tracking the intercostal neurovascular bundle along the chest wall, retropharyngeal abscess from a cervical lesion, and presacral and pelvic retroperitoneal abscess from a lumbar lesion. A psoas abscess usually arises from thoracolumbar tuberculous lesions below the diaphragmatic attachment to the spine. Psoas abscesses are pathognomonic of spinal TB and can present bilaterally in various sizes (Figs. 123.7A and B). Cold abscess can also present in the inguinal region commonly or can track distally into the thigh or calf region rarely (Figs. 123.8A to D). Lumbar psoas abscesses can also present at the Petit's triangle, in the ischioanal fossa and in the buttock under gluteus maximus. The abscess can spread along the perineural spaces, e.g. from the cervical spine, along the brachial plexus sheath into

Fig. 123.6: The extent of abscess formation in tuberculosis does not match the severity of vertebral damage. The lumbosacral radiographs of this patient do not show any vertebral damage. But the patient has extensive abscesses collected in the paravertebral, pelvic, and iliac regions. Except for back pain, he was asymptomatic.

Table 123.1: Location of cold abscess and their pathways of spread from the primary spinal focus.	
<i>Paths of spread</i>	<i>Presenting region</i>
Cervical spine	
Prevertebral fascia	Retropharyngeal abscesses
Prevertebral fascia	Mediastinum to enter trachea, esophagus, or pleura
Deep cervical fascia	Posterior to the sternomastoid muscle (posterior triangle of neck)
Thoracolumbar spine	
Intercostal nerves	Chest wall
Ilioinguinal and iliohypogastric nerves	Rectus sheath and lower abdominal wall
Psoas sheath	Thigh
Posterior spinal nerves	Paraspinal region
Superior gluteal nerve	Buttock
Flat muscles of abdominal wall	Petit's triangle
Internal pudendal nerve	Ischiorectal fossa

Figs. 123.7A and B: Huge bilateral psoas abscess (arrows) in a patient with thoracolumbar tuberculosis (A). The anteroposterior radiograph shows paraspinal soft tissue widening due to the abscess which is confirmed in the axial magnetic resonance imaging (B).

Figs. 123.8A to D: The tracking of a psoas abscess shown through serial sagittal images. The abscess that develops in the disc and adjacent vertebral body (A), tracks along the neural foramen and the psoas sheath (B and C), and forms a huge paravertebral psoas abscess (D).

medial side of arm, from the sacroiliac joint along the sciatic nerve into the gluteal region, posterior thigh and the calf muscles. It can also spread along the perivascular spaces (e.g. along the aorta and its branches, along the femoral vessels into the thigh, either deep along the femoral canal or present superficially in the femoral triangle, along the obturator vessels into the adductor region, along the branches of internal iliac vessels into the gluteal region, along the brachial artery into arm, etc.).

Deeper abscesses are not clinically palpable but can present with pressure symptoms. A retropharyngeal abscess arising from cervical TB can produce dysphagia and dysphonia. Some posterior compartment abscesses in the erector spinae and those from the sacroiliac joints can be palpable. They may present as a tender fullness elevating the overlying muscles. Abscesses presenting superficially have the typical features of cold abscesses. Abscesses in patients treated early with antitubercular chemotherapy resolve gradually (Figs. 123.9 and 123.10). If left untreated, thinning of the skin by pressure and inflammation can result in rupture of abscess. Once the abscess contents are discharged, persisting infection in the walls of the abscess

cavity leads to the formation of a sinus. The sinus may heal spontaneously after all the necrotic material is discharged or may continue for long periods if there is any residual pyogenic or tubercular infection (Figs. 123.11A to E). The tubercular pus is white or light grey in color, watery, and has no specific smell unlike a pyogenic abscess.

Tubercular Kyphosis

As the disease progresses, collapse of the vertebral body is evident as a localized kyphotic deformity. Significant involvement of a single vertebral body manifests as a prominence of a single spinous process termed as a knuckle deformity. Involvement of two or three adjacent vertebral bodies manifests as a sharp, angular kyphosis called the *gibbus* and involvement of multiple adjacent vertebrae manifests as *global rounded kyphosis*. With progressive destruction and further destabilization, sagittal, coronal subluxations, or rotatory translations can occur, leading to catastrophic neurological complications. Lesions of the cervical and lumbar region tolerate vertebral destruction without evident kyphosis due to their inherent lordosis, whereas thoracic lesions present earlier with significant

Figs. 123.9A and B: Resolution of abscess following appropriate antitubercular treatment. The coronal and sagittal magnetic resonance images show resolution of the huge paravertebral psoas abscesses and the epidural abscess after successful antitubercular chemotherapy and surgical stabilization. Coronal magnetic resonance image of a patient with huge paravertebral psoas abscesses on the right psoas muscle is shown in (A). The abscess has completely resolved in the follow-up MR image (B) after successful anti-tubercular chemotherapy and surgical stabilization.

Figs. 123.10A to C: Sagittal magnetic resonance imaging (MRI) of a patient with L3–L4 tubercular spondylodiscitis (A). The patient was treated with adequate chemotherapy and declared healed after 9 months. Follow-up MRI performed at 3 years shows fatty replacement of the vertebral body and healing of the lesion (B). However, coronal MRI shows the presence of residual cold abscess on one side (C). These abscesses are considered “sterile” and are not treated by medical or surgical methods, if the patient does not have any clinical features of disease activity.

deformity. Uncommon types like the posterior element involvement and the nonosseous type do not present with kyphotic deformity.

In all patients, the kyphosis progresses during the active stage of the disease and the final deformity is related to the extent of vertebral body loss and the spinal level

Figs. 123.11A to E: Typical healing of a tuberculous sinus. Posterior surgeries for active spinal tuberculosis carry a risk of persistent abscess drainage with delay in wound healing. This patient with T10-T11 tuberculosis had been treated by posterior stabilization and global reconstruction (A and B). The patient developed a sinus through the surgical site. Clinical photographs of the sinus taken at 6 weeks (C), 12 weeks (D) and 4 months (E) show good healing of the sinus eventually with continuous chemotherapy.

of involvement. Complete destruction of each vertebral body can account for a final kyphosis of approximately 30° and this is a little more in the children and thoracolumbar junctional lesions. In children, the kyphosis continues to progress until the period of growth is complete (Figs. 123.12A to E). Hence, all children need continued follow-up till the entire growth potential is completed. Rajasekaran has described the “spine at risk” radiographic signs where

children at potential risk for progressive kyphosis can be identified at an early stage (described later).

Neurological Deficit

Neurological involvement occurs in up to 20% of the patients with spinal TB.⁶ Since thoracic and the thoracolumbar regions are the common regions afflicted

Figs. 123.12A to E: Lateral radiograph of thoracolumbar spine of a child with spinal tuberculosis treated by chemotherapy. The kyphosis angle is 30° at the end of treatment that progressively has worsened to 115° at the end of 15 years. Post-tubercular kyphosis can worsen in children and can be effectively predicted and prevented by looking for the “spine-at-risk” signs. This child has had posterior retropulsion and toppling sign positive and hence has developed progressive kyphosis.

Table 123.2: Stages of tuberculous paraplegia.

Patient is asymptomatic Neurological examination reveals an extensor plantar response or ankle clonus
↓
Patient has incoordination while walking but can walk with support
↓
Patient is confined to bed due to severe spastic weakness (“paraplegia in extension”) Varying degrees of sensory blunting present
↓
“Paraplegia in flexion” with bladder, bowel involvement, and flexor spasms
↓
Flaccid paraplegia

by TB, lower limb weakness with bladder and bowel involvement are the usual neurological symptoms. Neurological involvement initially presents as incoordination and clumsiness while walking and slowly progresses to paraplegia (Table 123.2). Cervical tuberculous lesions manifest with quadriparesis.

Neurological deficits can occur both in the active phases of the disease and even after complete healing. In active lesions, it is due to the result of direct compression of the spinal cord by an abscess, inflammatory granulation tissue, a dislodged sequestrum, or canal compromise due to instability. In the late stages, it is usually due to stretching of the cord over a bony ridge at the apex of the deformity (Figs. 123.13A to D and Table 123.3).

Since TB affects the vertebral bodies predominantly, the spinal cord compression starts anteriorly with a gradual

increase in the spasticity that may not be appreciated by the patient initially but evident by exaggerated reflexes and an extensor plantar response. As compression increases, the anterior and lateral columns of the cord are affected gradually leading to complete motor loss and reduction of sensations (pain, temperature, and crude touch). Later, the posterior column is also affected leading to complete loss of fine sensation and disturbances of sphincters. In long-standing compression, the spasticity is replaced by flaccidity. The neurological deficit could be categorized into the following stages⁷:

- **Stage I:** The patient does not appreciate weakness but the clinician notices clumsiness of gait and signs suggestive of cord compression.
- **Stage II:** The patient has evident motor weakness but the power is sufficient that he/she manages to walk (motor power grade 3 or above).
- **Stage III:** Bedridden (severe motor weakness) with paraplegia and sensory loss <50%.
- **Stage IV:** Complete motor weakness with loss of sensation >50% and/or bladder bowel involvement and/or flaccid paraplegia and/or paraplegia with flexor spasm.

DIFFERENTIAL DIAGNOSIS

Tuberculosis is often over-diagnosed in endemic areas and under diagnosed in developed countries. It should be differentiated from other granulomatous lesions like fungal spondylitis, metastatic and primary spinal tumors, and pyogenic spondylitis. Typical paradiscal involvement, minimal or absent clinical signs of sepsis, presence of a

Figs. 123.13A to D: Clinical photographs of a child affected by spinal tuberculosis at the age of 4 years. Though the deformity looks minimal at the completion of chemotherapy, it has significantly worsened by adolescence. Magnetic resonance imaging shows a buckling collapse with cord compression and neurological deficits. A coronal section at the apex of the deformity actually shows two vertebrae overlapping each other due to the buckling.

large abscess and characteristic findings on the MRI (*see below*) help to confirm the diagnosis of spinal TB.

■ INVESTIGATIONS

Laboratory Investigations

The standard blood test performed is the erythrocyte sedimentation rate (ESR). It may be markedly elevated

(>70 mm/h) and serial ESR measurements are also helpful in assessing the response to treatment. It generally normalizes within 3 months of antitubercular treatment. Failure to normalize should spur one to identify causes for the same including primary drug resistance or alternate etiology. Erythrocyte sedimentation rate, however, lacks specificity and cannot help to differentiate noninfectious causes such as malignancy. C-reactive protein (CRP) has been found to be elevated in up to 71% of patients with spinal TB.⁸ It scores slightly over ESR in that it is specific for infectious or inflammatory lesions. Changes in CRP levels take about 14 days, while ESR takes about 4 weeks to demonstrate and hence more useful in monitoring treatment response.

The role of tuberculin skin test (Mantoux) as a diagnostic tool in the present era is unclear. The tuberculin test is positive in 62–100% of patients with TB.⁹ A positive Mantoux test merely indicates cell-mediated immune response due to a previous tuberculous infection, and in endemic regions, the test can be positive even in patients without active TB. Coexistent infection by human immunodeficiency virus and other immune deficiency conditions can also give a false-negative skin test. Its diagnostic value is high in regions where TB is rare, and in endemic areas, it can at best be considered only as a corroborative evidence for TB.

Serological tests using enzyme-linked immuno assay have tested antibody response to various TB antigens, including A-60, CFP-21, ESAT-6, MPT-63, and MPT-64.

Response of IgM and IgG antibodies has also been studied. Jain et al. reported a fall of IgM titer and rise of IgG titer following 3 months of successful treatment. Though it has a high specificity, it has low sensitivity in disease endemic countries with a high infection rate. In equivocal cases of spinal infection, serologic tests for brucellosis should also be carried out in view of striking similarity in the presentation of both diseases. Serological tests for brucellosis are considered positive if the antibody titer is more than 1:80.

Polymerase chain reaction (PCR) analysis especially from tissue samples is considered very sensitive and specific for the diagnosis of spinal TB. Tuberculosis PCR from tissue aspirate has a sensitivity of 73.1%, specificity of 93.7%, and low false-positivity rates (13.6%).¹⁰ The positive agreement between histopathology (the gold standard for confirmation of diagnosis) and PCR is reported to be very good (0.69).

If TB is confirmed, the treating physician needs to perform a baseline liver function test before initiating chemotherapy. Most antitubercular drugs are potentially hepatotoxic and hence knowing the pretreatment functional status of the liver is essential.

Bacterial Culture

Bacterial culture of the infected tissue is useful to confirm the diagnosis and to acquire antibiotic sensitivities to guide therapy. Since extrapulmonary tuberculous infection is paucibacillary, it is essential to culture material from deep structures such as bone and abscess walls rather than culturing pus.

The most common solid medium is Lowenstein-Jensen (L-J), an egg-based medium. Positive detection rate with this method in spinal TB has ranged from 0% to 75%.¹¹ Though widely available, its major drawback is the prolonged time for identifying growth. Also, if a drug sensitivity report is necessary, it can be carried out only after the initial growth.

Agar media such as Selective 7H11 and liquid-based media (Becton-Dickinson and Co, BACTEC and BACTEC MGIT) now are the standard. Typical hold periods after which growth can be clearly identified are 4–6 weeks. An important use of these systems is that they allow drug susceptibility assessment. This helps in identifying drug-resistant strains and start early alternate second-line medications. This method relies on the metabolism of ¹⁴C-labeled palmitic acid leading to ¹⁴CO₂ that is quantified using specific instruments. In a comparative study, BACTEC and L-J media gave positive results of 83.87% and 61.29%,

respectively, with the average detection time being 11.3 days and 26.7 days, respectively.¹²

Histopathology and Microbiology

The confirmation of TB infection is through identification of bacillus in the tissue or by histological confirmation of typical tubercles in the infected tissue. Typically, 10^{4–6} organisms per milliliter are required in the infected tissue for detection of the bacilli. Bone tissue or abscess samples are obtained to stain for acid-fast bacilli and isolate organisms for culture and sensitivity. Acid-fast staining and culture results are positive in only about 50–60% of the cases, since skeletal TB is considered as a paucibacillary type.¹³ So, the tissue should be sent for histopathological examination. The typical histopathological findings are large caseating necrotizing granulomatous lesions with epithelioid and multinucleated giant cells with lymphocytic infiltration. The method most widely used to acquire the tissue sample is CT or fluoroscopy-guided needle/trocar biopsy. In endemic countries because of high prevalence, chemotherapy is sometimes started without a definite microbiological diagnosis. This is based on the typical clinical presentation and radiological features. However, a tissue biopsy is needed in patients with atypical findings, lack of expected response to drug therapy, suspicion of drug-resistant strains, and in patients from nonendemic places.

Imaging Studies

Earliest features observed on plain radiographs are vertebral osteoporosis, narrowing of the joint space, and indistinct paradiscal margin of vertebral bodies. Progressive destruction leads to vertebral collapse, kyphosis and sagittal or coronal instability. Involvement of multiple adjacent vertebra leads to wedging and a smooth, kyphotic deformity. In the cervical spine, the prevertebral soft tissue shadow can be enlarged due to distension of the abscess in the retropharyngeal region. In the thoracic spine, the cold abscess is visible on anteroposterior plain radiographs as a fusiform or globular radiodense shadow (*bird's nest appearance*) (Figs. 123.14A to C). Long-standing abscesses may produce concave erosions around the anterior surfaces of the vertebral bodies called *the aneurysmal phenomenon*.

Computed tomography and MRI can detect lesions at an earlier stage. Computed tomography is useful in assessing accurately the extent of bony destruction, early identification of posterior element involvement, and in TB of

Figs. 123.14A to C: Sagittal and coronal magnetic resonance imagings demonstrate thoracic spinal tuberculosis with perivertebral abscess formation (A and B). The anteroposterior radiograph of the thoracic spine shows the paravertebral abscess collected in the paraspinal region, indicated by yellow arrows (C).

Figs. 123.15A to C: Computed tomographic scans are quite helpful in identifying junctional “hidden” region of the spines. This patient had neck pain and neurological symptoms, and radiographs of the cervicothoracic spine shows only pedicular asymmetry on the right side in the anteroposterior view. The sagittal scan shows significant destruction of the upper thoracic vertebrae and retropulsion causing canal compromise.

Table 123.4: The different signal intensity changes in spinal cord as observed in MRI.

Cord edema: Spinal cord shows diffuse hyperintensity in T2-weighted images and diffuse hypo or isointensity in T1-weighted images.

Myelomalacia: It is considered when irregularity of the spinal cord was associated with patchy hyperintensity in T2-weighted images and hypointensity in T1-weighted images.

Cord atrophy: It is described as apparent loss of cord size with relative increase of subarachnoid space.

Syringomyelia: Dilation of central canal with change in its signal intensity as that of CSF in T1- and T2-weighted images.

Thickening to dura-arachnoid complex: It is seen as thick hypointense ring in T2-weighted images around the cord obliterating the CSF space with relative increase of subarachnoid space.

Arachnoiditis: When normal CSF signal is replaced with irregular hypointensity in both T1- and T2-weighted images.

Extradural compression

Fluid shows as diffuse hyperintensity in T2-weighted images and hypointensity in both T1- and T2-weighted images.

Caseous tissue shows mild hyperintensity in both T1- and T2-weighted images.

Granulation tissue shows heterogeneous hypointensity or hyperintensity in T2-weighted images.

(MRI: Magnetic resonance imaging; CSF: Cerebrospinal fluid).

certain regions such as the craniovertebral and cervicodorsal junction, the sacroiliac joints, and the sacrum, which are not easily defined in the radiographs (Figs. 123.15A to C). Computed tomography is also helpful when a percutaneous biopsy is planned. *Magnetic resonance imaging* is the gold standard investigation for demonstrating the extension of disease into soft tissues and the spread of tuberculous abscess. It is the most effective method for demonstrating neural compression. Magnetic resonance imaging with contrast is also helpful in differentiating vertebral lesions from other noninfectious causes. Jain et al. have calculated the percentage canal occupancy based on CT/MRI in 15 cases of TB of spine from C3 to T12 with no neurological deficit and found that up to 75% canal occupancy by the extrinsic compressive element like abscess, sequestrum was found compatible with intact neurological state.¹⁴ However, besides cord compression, when other causative factors are added to pathogenesis of paraplegia such as vascular cause or mechanical instability, it can produce paraplegia at a lesser canal compromise (Table 123.4). It was observed that patients with relatively preserved cord size with evidence of only myelitis/edema respond well to antitubercular treatment with or without surgical decompression. Predominantly fluid collection in extradural space also resolved well with anti-tubercular treatment (ATT) alone. In patients with extradural collection with cord compression and myelitis, improvement in neural deficit was noted if surgical decompression was performed early. Patients having significant cord compression and myelomalacia did not show favorable response even after surgical decompression and had probably developed irreversible changes.

Serial MRI can be used to assess the response to treatment and regression of the disease. The healing of the vertebral lesion is diagnosed on follow-up MRI as complete resolution of marrow edema, replacement of marrow by fat seen as a bright signal on T1- and T2-weighted images, and complete resolution of paravertebral collections (Figs. 123.16A to D). However in a study by Jain et al., out of 49 patients, only 20 had complete radiological features of healing.¹⁵ So presence of residual cold abscess in the follow-up MRI despite successful chemotherapy is not an indication for surgery. *Bone scan* with Tc-99m is considered to be highly sensitive, but nonspecific. It may only aid to localize the site of active disease and to detect multilevel involvement.

TREATMENT

General supportive measures include bed rest, external bracing, nutritious diet and vitamins as required, care of bladder and bowels, and good nursing care. Modern anti-tubercular drugs are able to achieve therapeutic levels in caseous tissues and abscesses and excellent clinical cure can be achieved. Hence, uncomplicated spinal TB is considered as a medical disease with selected surgical indications. Ambulant multidrug chemotherapy is administered for all the patients, and bed rest with external bracing is advised in the initial period. The patient is followed at periodic intervals with clinical examination, radiographs, and assessment of ESR and CRP levels till complete healing is achieved. Surgical treatment is recommended for certain specific indications in these patients.

Figs. 123.16A to D: Coronal magnetic resonance imaging (MRI) of a patient with T12–L1 tuberculosis and huge abscess on the right side (A). Post-treatment MRI reveals complete resolution of abscess (B).

Antitubercular Chemotherapy

The treatment of spinal TB is primarily medical with antitubercular chemotherapy. Compliance with chemotherapy is the most important determinant of treatment outcome in spinal TB. All patients of spinal TB diagnosed before destruction has occurred (based on MRI) or patients with minimal destruction of vertebrae can be treated with chemotherapy alone. Ambulant chemotherapy, where no specific instructions for rest or activity restriction are advised, has equivalent results to institutional chemotherapy and hence preferred. Successful treatment requires the prolonged administration of antituberculous drugs (6 or 9 months). A combination of drugs is essential to prevent emergence of resistant strains. In developing countries, to ensure drug compliance, DOTS (Directly Observed Treatment Short course) has evolved. This ensures uninterrupted supply of medication and prevents the emergence of multidrug-resistant tuberculosis (MDR TB) to a large extent.

The World Health Organization guidelines for the type and duration of antituberculous chemotherapy consider spinal TB to be severe extrapulmonary (category 1) and treatment is advised for 6 months. In cases of relapse or treatment failure, treatment is prescribed according to category 2, i.e. for 9 months. The currently recommended first-line drug regime is four-drug therapy. This includes isoniazid 5 mg/kg, rifampicin 10 mg/kg, pyrazinamide 20–25 mg/kg, and ethambutol 15 mg/kg for 2 (category 1) to 3 months (if category 2) followed by isoniazid and

rifampicin for 4 (category 1) to 6 months (if category 2). In children, ethambutol is replaced by streptomycin, as it may cause optic neuritis. The British Medical Research council studies have conclusively proved that short-course chemotherapy for spinal TB is effective.¹⁶ However, their studies did not include patients with multiple vertebral involvement, cervical lesions, or those with major neurological involvement. Because of this limitation, many experts recommend 9–12 months of treatment. The exact duration of chemotherapy should be individualized. Treatment protocol of HIV-positive patients is same as of HIV negative. HIV patients with lower CD4 counts have poor prognosis.

Monitoring Treatment Response

Patients are monitored based on clinical, hematological, and radiological criteria. Usually after 8–10 weeks of starting chemotherapy, the patient begins to feel well, regains his appetite, and gains weight. The spinal pain and the muscle spasm reduce. Radiologically, the bony destruction may increase in the first 6 weeks. Thereafter, the bony destruction stops. Abscess shadow begins to decrease in size after 3–4 months and gradually regresses. The sclerosis of the bone begins by 3–4 months. At the end of 6 weeks to 2 months, the clinician is able to judge the patient's response to treatment. If a new lesion appears or the original lesion is progressing further, drug resistance should be suspected. Surgery is often necessary at this stage.

Patients are typically seen at 6-week intervals for the first 3 months and at 2-month interval till completion of

chemotherapy. The patients are monitored at intervals of 6 weeks for hepatotoxicity, optic neuritis, and renal function. Radiographs of the spine are also repeated at intervals of 6 weeks to monitor the kyphosis and the resolution of abscess shadow. At the end of 9 months of treatment, patients are assessed on clinical, radiological, and hematological grounds. The disease often becomes quiescent at this point of time. There will be no pain, muscle spasm, abscess, sinus, or neurological deficit. X-ray reveals sclerosis of the lesion. Children should be managed on the same lines as adults with appropriately adjusted doses but should be followed up to skeletal maturity as the kyphosis can deteriorate with growth.

Drug Resistance

Multidrug-resistant TB has been reported in 2.3% patients among the new cases and 17.2% among the previously treated cases. Drug-resistant TB is defined as a case of TB due to bacilli resistant to one or more antitubercular drugs. Multidrug-resistant TB is defined as disease due to *M. tuberculosis* that is resistant to isoniazid (H) and rifampicin (R) with or without resistance to other drugs. Extensively drug-resistant TB is defined as resistance to isoniazid (INH) and rifampicin along with further resistance to any fluoroquinolone and at least one injectable second-line drug.

Treatment regimens for MDR TB spine have to be tailor made according to the drug sensitivity profile of each patient. Diabetes and HIV are more frequently associated with drug resistance making treatment even more difficult.

The treatment principles for MDR TB include:

- Treatment to be supervised by qualified physicians only.
- Drug sensitivity testing should be used to guide therapy.
- Regimens should consist of a minimum of four new drugs not used previously.
- An injectable aminoglycoside should be used for a minimum period of 2 months.
- Treatment should be for a minimum duration of 24 months.

Patients on second-line drugs for resistant TB need to be monitored carefully for side effects. Complete blood counts, renal and liver function tests are performed monthly. Gastrointestinal side effects are the most common. Hepatotoxic drugs need to be stopped if the liver enzymes are five times increased from their normal values. Drug induced neuropathies can be prevented by the addition of pyridoxine to the treatment regimen from the outset.

Surgical Treatment

The indications for surgery in spinal TB are to obtain tissue sample for biopsy, drain an abscess cavity, decompress the spinal cord, achieve debridement of disease focus, and stabilize the spine. The evolution of surgical treatment of spinal TB has passed through different phases of development. The introduction of antitubercular drugs in the 1940s revolutionized the treatment and made surgery eminently possible.

In the pre-antitubercular era, nonoperative treatment in the form of body casts and braces invariably resulted in deformity, contractures, or death. Such disappointing results of nonoperative treatment motivated surgeons to develop surgical techniques for excision of the diseased tissue. Without chemotherapy, such procedures obviously resulted in persistent sinus and ulcer formation and death in many patients. Chipault (1896) was the first to perform laminectomy for paraplegia due to TB.¹⁷ However, the lamina was the only stabilizing structure in a spine where the anterior vertebral bodies are already destroyed. So, laminectomy procedures invariably resulted in poor results and hence the procedure was abandoned. Subsequently, anterolateral decompression through costotransversectomy approach was developed. Norman Capener (1933) is credited for the first “anterolateral decompression” procedure which he named as “lateral rhachiotomy.”¹⁸ This was performed by excising a part of the lamina and pedicle from one side to enter the spinal canal anteriorly and relieve the pressure on the spinal cord. In the absence of chemotherapy, the techniques fell into disrepute due to the high incidence of sinus formation and secondary infection. Because “direct operation on the diseased area” presented such a gloomy picture, surgeons developed “distant operations” without opening the pathological site. Albee and Hibbs (1911) introduced the posterior spinal fusion to shorten the period of immobilization.¹⁹ But as the anterior diseased tissue was not dealt with, the mycobacterium persisted with possibilities of flaring up with a drop in immunity.

The introduction of antitubercular chemotherapy achieved spectacular success in the control of disease. The availability of effective antitubercular drugs made direct surgery on the diseased area possible without dissemination of infection or sinus formation. Surgical debridement of tuberculous infection was performed through the anterior approach based on the premise that “anterior disease needs anterior surgery,” thus preserving the stable

Table 123.5: Conclusions from the different Medical Research Council (MRC) trials.

Center	Conclusions
Masan, Korea—MRC 1973	The standard drugs were potent for florid spinal tuberculosis in children and bed rest was not necessary
Pusan, Korea—MRC 1973	Streptomycin is not necessary and Plaster-of-Paris jacket offers no benefit
Bulawayo—MRC 1974	Debridement is not a good operation and clinical diagnosis assisted with radiographs was sufficient to start the treatment as was later confirmed by histopathology and/or bacteriology in 83% of patients
Hong Kong—MRC 1974	Radical anterior excision is a better operation with positive histopathology (HP) and/or bacteriology in 85% of patients
Madras—MRC 1978	Ambulatory treatment with rifampicin and isonicotinic acid hydrazide for 9 months was found to be superior to ambulatory 6 months regimen or 6 months regimen with radical resection within 1 month of start of chemotherapy

Figs. 123.17A to D: Diagram of the radiological signs for the “spine at risk.” (A) *Separation of the facet joint:* The facet joint dislocates at the level of the apex of the curve, causing instability and loss of alignment. In severe cases, the separation can occur at two levels. (B) *Posterior retropulsion:* This is identified by drawing two lines along the posterior surface of the first upper and lower normal vertebrae. The diseased segments are found to be posterior to the intersection of the lines. (C) *Lateral translation:* This is confirmed when a vertical line drawn through the middle of the pedicle of the first lower normal vertebra does not touch the pedicle of the first upper normal vertebra. (D) *Toppling sign:* In the initial stages of collapse, a line drawn along the anterior surface of the first lower normal vertebra intersects the inferior surface of the first upper normal vertebra. “Tilt” or “toppling” occurs when the line intersects higher than the middle of the anterior surface of the first normal upper vertebra.

posterior arch and ligament complex. Direct access to the anterior disease focus permitted complete clearance of the abscess, provided tissue biopsy for diagnosis and insertion of strut rib grafts to reconstitute the anterior column.

Hodgson in 1960s popularized the concept of anterior surgery with radical debridement²⁰ and placement of rib strut grafts (*The Hong Kong Surgery*), a concept originally described by Ito et al. The complications included the morbidity of anterior approach in patients who invariably had

poor pulmonary function, vascular complications, prolonged surgeries, neurological deficits, and the problems of huge anterior bone defects.²¹ Graft-related complications such as displacement, breakage, and late recurrence of a kyphus have been reported in up to 40% of patients.²²

While the morbidity of radical excision surgeries were increasingly being recognized, Tuli observed that the potential for repair and regeneration of the diseased vertebrae with multidrug combination chemotherapy was significant. Hence, surgical treatment should be reserved for select situations only (*middle path regimen*²³). The results of the series of studies by the British Medical Research Council Working Party on Tuberculosis of the Spine performed in 1965 in Korea, Zimbabwe, Hong Kong, and Madras supported this view (Table 123.5). Over time with the development of “middle path regimen,” indications for surgery have become universally more selective, less for controlling disease and more for preventing and correcting spinal deformities and neural complications and for improving the quality of function.²⁴

The natural history of progress of deformity in childhood spinal TB is different from that of adults, in that continued progression of deformity even after complete healing of disease has been observed in about 40% of children in a longitudinal study.²⁵ So it is important to identify such children at potential risk for progressive deformity during the active stages of disease, as they would benefit from early surgery. Rajasekaran evaluated the evolution of deformity in childhood spinal TB and described four “spine at risk” signs as indicators of poor prognosis for gross kyphosis mandating surgical treatment²⁶ (Figs. 123.17A to D). The loss of integrity of the facet joints was the common determining factor in all the four signs. These

Table 123.6: Indications for surgery in spinal tuberculosis.

Neurologic deficit
Severe neurological deficits at presentation
Rapidly worsening deficits
New onset or deteriorating deficits during chemotherapy
Unimproved deficits after 6–8 weeks of chemotherapy
Spinal instability
Panvertebral disease
>3 contiguous vertebra involved
Vertebral body loss >1 in thoracic spine and 1.5 in lumbar spine
Children with initial kyphosis >30°
Children with “spine at risk” signs
Posterior neural arch with pedicular destruction
Clinical instability
Late deformity
Severe kyphosis with late onset neurological deficits
Lack of clinical response to chemotherapy
Failure of clinical improvement after 6 weeks of chemotherapy
Disease recurrence despite chemotherapy
Primary drug resistance

signs appear early in the course of the disease at which time it is much easier to do a prophylactic surgical fusion and column reconstruction. Such prophylactic surgery would be useful to prevent late complications like “buckling collapse” and late onset paraplegia.

Different Surgical Techniques

Currently, surgery in spinal TB is performed to achieve any or all of the following aims:

- Debridement and drainage of large cold abscesses
- Decompression of spinal cord and neural structures
- Spinal deformity correction using spinal instrumentation
- Reconstruction of the anterior column
- Stabilization of the spine with anterior and/or posterior instrumentation.

These goals can be achieved through different surgical approaches and decided on an individual basis (Table 123.6). The different surgical techniques can be grouped under the following approaches:

1. *Anterior decompression and reconstruction through an anterior approach:* The vertebral body reconstruction may be performed using a variety of grafts such as ribs, iliac crest, fibular graft, or even allografts. In the

last few years, reconstruction by titanium cages is used very successfully. Stabilization is achieved by anterior instrumentation, either plates or rod systems. The limitations of anterior approach include poor access to the upper thoracic spine, lower lumbar and lumbosacral spine, working around a diseased lung, risk of injury to viscera, vascular structures, sympathetic chain and thoracic duct, inadequate deformity correction, and a higher morbidity of the approach. A combined anterior plus posterior procedure helps overcome some of the instrumentation-related drawbacks of the isolated anterior operation. However, it entails two operations with associated additional morbidity.

2. Posterior instrumentation and anterior decompression performed through two separate approaches in single or two stages. This is indicated in patients with significant vertebral destruction and kyphosis, where anterior decompression with reconstruction of the anterior column and posterior stabilization are mandatory.
3. An “all posterior approach” is becoming increasingly popular. The decompression, reconstruction of the anterior column, and instrumentation are all achieved from the posterior approach. Anterior reconstruction of vertebral defects up to one vertebral level can also be performed through a transpedicular or anterolateral route through the posterior approach.

The availability of pedicle screw systems that provide excellent reconstruction possibilities along with the development of surgical techniques that allow anterior reconstruction through a posterior approach have tilted the balance in favor of posterior surgeries in spinal TB. The safety of use of titanium pedicle screw system even in the presence of abscess has enabled the extensive use of this system even in active spinal TB. Though there was initial apprehension to use metal implants in active infection, it was proven by Oga et al. that the tubercle bacilli unlike pyogenic organisms does not adhere to metal and form any biofilm.²⁷

Surgical Techniques

Anterior Techniques

The most common region of the spine involved in TB is the vertebral body. Therefore, it is logical that an anterior surgery to decompress and reconstruct the spine would be the ideal approach. Anterior surgery offers the advantage of direct access to the diseased region, visualization of neural structures while debridement and decompression,

Figs. 123.18A to C: Lateral radiograph and sagittal magnetic resonance imaging show C4 vertebral body tuberculosis with kyphosis causing cord compression (A and B). The lesion has been treated by anterior debridement, iliac crest autograft reconstruction, and stabilization with a plate (C).

and the ability to insert strut grafts in the space created after debridement. Anterior decompression surgeries performed in the 1980s involved radical removal of the entire vertebrae that were involved. We now know that removal of the infected foci up to bleeding normal bone is sufficient, as the chemotherapy is efficient in clearing the residual infection. The use of a cage and bone grafts allows for more secure, accurate, and dependable deformity correction. The cage provides a more rigid fixation construct and minimizes the risk of graft subsidence or dislodgement.

Current standard practice is to use either cages with bone grafts or structural allografts supplemented with anterior or posterior instrumentation. The commonly used anterior instrumentation is screws placed in the vertebral body connected through rods. Single screw rod suffices in most patients but double screws may need to be inserted, if the kyphosis corrected has been significant or the vertebral dimensions are wide.

The standard surgical approach for the subaxial cervical spine is the anterior decompression and reconstruction. Posterior techniques are not used in cervical spine as they impede any anterior decompression, provide only weak bone anchors and the comparative ease of anterior surgery in the cervical spine. The anterior approach to the cervi-

cal spine exposes the anterior vertebral bodies from C3 to T1 (Figs. 123.18A to C). It is used for debridement and reconstruction, biopsy of vertebral bodies and disc spaces and drainage of abscesses. If the level of pathology is localized, a transverse skin crease incision is made at the appropriate level of the vertebral pathology.

Technique—Cervical Spine

The incision should extend obliquely from the midline to the posterior border of the sternocleidomastoid muscle. The fascial sheath over the platysma is incised in line with the skin wound using the fingers, gently retracting the sternocleidomastoid muscle laterally. A plane is developed between the medial edge of the carotid sheath and the midline structures (thyroid gland, trachea, and esophagus), cutting through the pretracheal fascia on the medial side of the carotid sheath. The sheath and its enclosed structures laterally with the sternocleidomastoid muscle are retracted. Occasionally, either or both of the thyroid arteries that connect the carotid with the medial structures may have to be divided to open the plane. After splitting the pretracheal fascia by blunt dissection the cervical vertebrae are visualized, covered by the longus colli muscle and the prevertebral fascia. Once the prevertebral fascia is

Figs. 123.19A to C: Magnetic resonance imaging of a patient with back pain shows destruction at D11–12 levels with abscess formation and kyphosis. Anterior reconstruction at the dorsolumbar junction has been performed using mesh cage and dual screw vertebral fixation.

incised, the abscess collected beneath it is let out completely. The longus colli muscles are held retracted on either side by self-retaining retractors. Thorough debridement of the necrotic tissue is done with curettes, high speed burr, and rongeurs. In case of corpectomy, the discs on either side are removed first followed by removal of the body. It is ensured that the spinal cord is decompressed adequately. An appropriate sized cage or allograft is tapped into place and secured with plates and screws.

Technique—Thoracic and Thoracolumbar Spine

In the thoracic spine, the affected vertebral body is reached through a standard thoracotomy. Either extrapleural or transpleural dissection is performed to access the vertebral body. Once the affected vertebral region is reached, the prevertebral fascia is incised to let out the tuberculous abscess. The segmental vessels over the affected vertebral bodies are ligated. The discs above and below the infected body is excised first. The necrotic bone tissue is removed by a combination of osteotome, nibbler, and high speed burr. The posterior vertebral cortex and the epidural granulation tissue are removed at the last. This prevents the dura from bulging inside the field during vertebral resection. After appropriate debridement, the defect is reconstructed with a cage or a structural allograft and supplemented with anterior stabilization (Figs. 123.19A to C).

Posterior Techniques

The advantages of the posterior approach include:

- Surgeon is familiar with the approach.
- Excellent exposure for circumferential spinal cord decompression.
- Instrumentation can be easily extended for multiple levels.
- Posterior instrumentation is stronger and allows better control of deformity correction
- Depending upon the approach, anterior reconstruction can be safely performed in addition to the posterior procedure.
- All the posterior approaches are extrapleural and hence preferred in patients with TB, where lung function may be poor and the lung may be adherent to the chest wall.

Posterior/posterolateral approaches can broadly be grouped into the following:

- Laminectomy
- Transpedicular
- Costotransversectomy
- Lateral extracavitary

Laminectomy

In the thoracic spine, a laminectomy alone offers exposure of the posterior epidural space only. It does not allow decompression anterior or anterolateral to the spinal cord.

Also, in patients with anterior vertebral involvement, a laminectomy creates a globally unstable situation that may potentiate instability and progressive kyphosis. Hence, it is useful and advocated only rarely when the vertebral body is unaffected but there is a posterior epidural mass compressing the spinal cord that needs to be excised.

Transpedicular Approach

The transpedicular approach serves as an excellent portal for debridement of the vertebral body and decompression of the spinal cord. A unilateral transpedicular approach offers >180° exposure of the spinal cord from midline posteriorly to slightly beyond the midline anteriorly, while a bilateral transpedicular approach would allow a circumferential decompression of the neural elements. Although cancellous chip grafts and cages up to 15–20 mm can be packed anteriorly, insertion of large strut grafts/cages >20 mm via the transpedicular approach is difficult due to the intact ribs (thoracic spine) and paraspinal musculature. Hence, this approach is not recommended when there is significant destruction of the vertebral body that requires reconstruction of the anterior column. A transpedicular approach is useful in patients where the primary problem is a neurologic deficit secondary to anterior or lateral compression of the spinal cord and when the structural integrity of the vertebral body is intact with only a minimal kyphotic deformity. However, adequate extent of fixation is mandatory to avoid implant-related complications (Figs. 123.20A and B).

The transpedicular approach utilizes the pedicle as a channel for entry anteriorly into the vertebral body and the adjacent disc for debridement of the infected focus. A posterior midline incision is taken. The muscles are dissected subperiosteally to the tip of the transverse processes. Pedicle screws are inserted cephalad and caudad to the diseased level and a rod is inserted on the side contralateral to the planned transpedicular approach. At the diseased level, adequate laminectomy is performed to relieve cord compression. The transpedicular approach is then started by using a pedicle probe and creating a tract across the pedicle into the vertebral body. A tap or a high speed drill is now used to widen the pedicle canal. The transverse process is resected at its base. If there is a large prevertebral abscess, the author prefers to gently dislocate the costotransverse joint with a Cobb elevator in order to drain the abscess. The lateral wall of the pedicle is now resected to allow more medial angulation for debridement of the vertebral bodies and the intervening disc. Once

the desired amount of debridement is achieved, then the medial pedicle wall is excised so as to access the anterior epidural space. The middle column consisting of the posterior wall of the vertebra along with the mass of epidural granulation tissue is then excised to decompress the neural elements. In patients with significant destruction of the vertebral body, a thorough anterior debridement through a bilateral transpedicular approach and shortening of the spine by applying compression across the diseased segment using the posterior pedicle screws and rods can be performed (Figs. 123.21A to F). Decortication is then done and bone graft laid over the decorticated surfaces for good fusion. A cross-link can be used if additional stability is necessary.

Costotransversectomy

The costotransversectomy approach was originally described for drainage of a prevertebral abscess secondary to thoracic TB. It involves excision of the medial 4 cm of the rib along with the rib head to gain a more oblique access anteriorly into the vertebral body. Since there is more room posterolaterally, a strut graft can be delivered into an anterior intervertebral defect and manipulated into position without having to retract the spinal cord. This approach is useful in patients where the disease is restricted to one or two levels (Figs. 123.22A to C).

The operation may be performed in the prone or lateral decubitus. Skin incisions described for this approach include longitudinal midline or paramedian, semicircular, oblique along the rib to be excised, or a T-shaped incision. With a T-shaped incision, where the horizontal component of the “T” is placed longitudinally along the midline and the vertical component placed transversely along the ribs, this approach can be used to perform circumferential decompression of the cord and simultaneous stabilization of the anterior and posterior columns. The authors prefer the midline longitudinal incision in the prone position. The paraspinal muscles are dissected from the midline subperiosteally and retracted to the tip of the transverse process. The paraspinal muscles are then divided horizontally at the level of the pathological vertebra to extend the lateral exposure. Posterior instrumentation is placed at the levels cephalad and caudad to the pathology, and a temporary rod is assembled on the contralateral side.

The medial 5 cm of the rib to be resected is exposed subperiosteally while preserving the intercostals neurovascular bundle. The costotransverse ligaments are cut and the rib is divided laterally at its posterior angle.

Figs. 123.20A and B: Posterior fixations for the treatment of tuberculosis should include at least two normal vertebral segments above and below the diseased segments. In this patient with T9–11 tuberculosis, four contiguous segments have been stabilized. In the follow-up radiographs, it is noted that the affected vertebra has collapsed leading to local kyphosis and implant pullout at the caudal fixation. The deformity did not progress further and healing occurred with complete resolution of the abscess.

Figs. 123.21A to F: (A and B) T2 sagittal and axial MR images of a 44-year-old patient showing spondylodiscitis involving the T6-T7 vertebra. The epidural abscess is causing cord compression. (C and D) AP and lateral radiographs of the same patient showing collapse of disc space and anterior vertebral erosion. (E and F) Postoperative lateral and AP radiographs show posterior stabilization involving two-adjacent segments. Posterior laminectomy and transpedicular decompression has been performed.

The transverse process too is cut at its base exposing the lateral surface of the pedicle. The rib is then followed up to its articulation with the vertebral body and disarticulated from the vertebral body. Excision of the rib opens up the

prevertebral abscess. More than one rib can be excised to offer a wider longitudinal exposure. The endothoracic fascia along with the parietal pleura is dissected off the vertebral body and pushed anteriorly exposing the lateral

Figs. 123.22A to C: Thoracolumbar tuberculosis in a child with destruction of multiple thoracic vertebrae T9–T10 (lateral radiograph—A). There is a huge prevertebral and epidural abscess causing cord compression in the sagittal magnetic resonance imaging. The lesion has been treated by a single stage, anterior debridement with fibular strut graft reconstruction, and posterior pedicle screw stabilization through a posterior approach.

part of the vertebral body. The intercostal vessels can be ligated and the intercostal nerve is traced back to the neural foramina. The ipsilateral lamina, facet joint, and pedicle are now excised at one or more levels. This allows access for decompression of the spinal cord posteriorly, laterally, and anteriorly. Debridement of the anterior vertebral body is then performed following which anterior strut graft or cage can be wedged into the anterior defect. Posterior rods are assembled and compression applied across the diseased segment to load the graft and hold it firmly in position. Decortication of the posterior elements is performed along with a posterior and intertransverse fusion.

Lateral Extracavitary Approach

The lateral extracavitary approach is essentially a lateral extension of a costotransversectomy. The more extensive rib resection provides a wider view of the anterior structures across the midline. This approach can be utilized both in the thoracic and lumbar spine. It is easier to perform in

the thoracic spine where the anterolateral surface of the vertebra is devoid of any musculature (Figs. 123.23A to H). Also the intercostal nerves can be sacrificed for improved exposure. In the thoracolumbar and lumbar spine, the muscles (including the diaphragm at L1) originating from the anterior and lateral surface of the vertebral body require to be dissected to get an adequate anterior exposure. Besides the lumbar nerves lying within the psoas muscles need to be handled carefully to prevent a post-operative neurological deficit.

In the prone position, a midline vertical incision is made that extends three levels above and below the pathological level. The lower part of the incision is gently curved laterally for about 5–6 in. The skin, subcutaneous tissue, the thoracolumbar fascia, and the trapezius or the latissimus dorsi are lifted up as a flap from the midline along the line of the incision. The flap is retracted laterally. A plane is defined along the lateral aspect of the erector spina muscles from where the muscles are elevated as a layer off the ribs and retracted medially. On the opposite side, the

Figs. 123.23A to H: All posterior global reconstructions of thoracic tubercular spondylitis. The patient has complete destruction of T6 vertebral body with epidural abscess and neurological deficit. He has been treated by posterior stabilization, decompression and anterior vertebral reconstruction with a cage.

spine is exposed to the tip of the transverse processes in the standard fashion. Posterior pedicle screws are inserted bilaterally as required. A rod is inserted into the screws on the contralateral side. On the ipsilateral side, the ribs are then dissected subperiosteally and divided at a distance of 10 cm from the costotransverse joint. The transverse process is excised at its base and the rib is dissected off the vertebral body and excised. Usually two to three ribs are excised to obtain an adequate exposure along the length of the anterior column. The endothoracic fascia along with the parietal pleura is then dissected off the vertebral body and pushed anteriorly. The segmental vessels are dissected off the vertebral bodies and divided after ligating them. The intercostal nerve is traced back toward the dura and the

nerve roots are ligated proximal to the dorsal root ganglion and divided. The pedicles along with the ipsilateral laminae and facets are excised so as to visualize the posterior, lateral, and anterior part of the spinal cord. The entire lateral surface and part of the anterior surface of the vertebra is visible. For performing a corpectomy, the disc above and below is identified and excised. The vertebra is then resected from laterally across leaving behind a thin shell of bone anteriorly and posteriorly. Then the entire posterior shell is pushed forward anteriorly before excising it.

The vertebral end plates are then prepared. An adequate size graft/cage is then wedged into the anterior defect about 1 cm anterior to the dural sac. The second posterior rod is then assembled and compression is applied across

the diseased segments in order to firmly hold the graft in position.

Transforaminal Approach

Posterior approaches have a more limited role in the lumbar spine because it is difficult to dissect the iliopsoas muscles from the lumbar vertebral bodies; the lumbar roots cannot be sacrificed making it difficult to perform complete vertebral body excision and reconstruction; and combined anterior with posterior surgery is preferred to a long posterior fixation to preserve lumbar motion segments.

Most commonly posterior surgery is limited to fixation for providing additional stability to the anterior construct. Another indication where the posterior approach finds a role in the lumbar spine is when the disease involves the peridiscal region of adjacent vertebral bodies resulting in severe pain, focal kyphosis, instability, or a neurologic deficit. Here, a PLIF (posterior lumbar interbody fusion) or a TLIF (transforaminal lumbar interbody fusion) like procedure has been used with great success. Indications for TLIF include the presence of localized kyphosis, presence of significant radiculopathy or neurologic deficit, or worsening of radiculopathy or neurologic deficit during ongoing chemotherapy resulting from presence of dural compression by diseased tissue.

A posterior midline approach is performed in the prone position. Pedicle screws are inserted at the involved levels or the adjacent vertebral body in case the amount of destruction at the involved level is excessive. The screws are fixed to a contoured rod on one side (lesser involved side neurologically and radiologically) with distraction at the involved segment. Psoas abscesses can be drained through the intertransverse window if required. Decompression of the neural elements is performed through a laminectomy. Epidural granulation and diseased tissue within the disc space is thoroughly excised. The anterior third of the disc space is packed with morselized bone graft, and an adequately sized interbody cage packed with bone is introduced. In some patients, only a cancellous autograft was used to fill the interbody gap. Pedicle screws on both sides are then fixed to precontoured rods under compression.

SURGERY IN HEALED TUBERCULOSIS

Modern antituberculous drugs have enabled a high rate of disease cure in spinal TB with good healing of the

lesion. Advances in imaging studies have helped to diagnose spinal TB in predestructive or early destructive phase obviating the need for surgery in many cases. Hence, most patients with healed TB are asymptomatic. Though complete cure may be achieved with chemotherapy, 3–5% of the patients end up with a deformity of $>60^\circ$.²⁸ The basic pathology in most patients with symptomatic healed disease is the development of kyphosis. Depending on the severity of deformity, the patient can present with persistent localized pain, costopelvic impingement, secondary cardiorespiratory problems, and late onset neurological deficits. Management of established kyphotic deformities can be difficult and fraught with complications.

Anterior, combined anterior and posterior, and posterior alone procedures have been described for the correction of established deformities, each having their own advantages and disadvantages. Anterior alone procedures have been reported for the correction of deformities in spinal TB. Adequate canal decompression, good correction of the deformity, and stabilization of the spine are the potential advantages. But such procedures are associated with difficulties in approaching the concavity of the angular kyphosis in deformities of $>60^\circ$ and hence did not gain popularity.

Kyphus correction surgery through combined approaches involves anterior corpectomy to achieve decompression, shortening of the posterior column, posterior instrumentation, and anterior and posterior bone grafting. Compared with other kinds of decompression techniques, anterior decompression has several advantages like direct access to the apex of the kyphosis, direct observation of tension of spinal cord at the time of correction of kyphosis, controlled decompression of the spinal cord, and it allows anterior strut graft fusion to stabilize the kyphosis. Posterior osteotomy can bring better correction of kyphosis, and combined anterior and posterior instrumented fusion can improve the rate of fusion. However, the disadvantage of the anterior-posterior procedure is the need for two surgical approaches to treat one pathology, resulting in increased blood loss, higher rates of infection, and prolonged surgical time.

The development of osteotomy techniques has advanced our ability to treat spinal deformities. The benefits of these techniques are that significant correction can be achieved at a single level. On the other hand, these techniques are often associated with significant bleeding, increased risk for neural injury, and are technically demanding to perform.

Figs. 123.24A to D: Posterior closing-opening wedge osteotomy to correct a post-tubercular kyphotic deformity. (A and B) Preoperative anteroposterior (AP) and lateral radiograph of the patient shows a kyphotic deformity of 118° at the thoracolumbar junction between T9 and L3 vertebrae. (C and D) Postoperative AP and lateral radiograph shows good correction of the deformity with pedicle screw instrumentation placed at least three levels proximal and distal to the apex. The “opened” anterior wedge has been reconstructed with a titanium mesh cage.

Posterior-only procedures for the correction of post-infection kyphotic deformities include transpedicular decancellation procedures, pedicle subtraction osteotomy, posterior vertebral column resection, and closing-opening wedge osteotomy. Deformities of smaller magnitude are corrected by decancellation procedures or pedicle subtraction osteotomy. More complex deformities require vertebral column resection procedures. The authors prefer a single-stage closing-opening wedge osteotomy to correct post-tubercular deformity of $>60^\circ$ (Figs. 123.24A to D). In a series of 17 patients who underwent this surgery, the average preoperative kyphosis improved from $69.2^\circ \pm 25.1^\circ$ to $32.4^\circ \pm 19.5^\circ$ postoperatively. The percentage correction of kyphosis achieved was $56.8 \pm 14.6\%$ (range 32–83%). The authors concluded that this technique is an effective method to correct severe post-tubercular kyphosis (PTK) with the advantage of being a posterior-only single-stage correction allowing for significant correction with minimal complications.²⁹

CONCLUSION

The poor outcome of TB of the spine that was once dreaded in the prechemotherapy era has improved significantly

after the availability of antitubercular drugs. The invention of modern diagnostic aids such as MRI and advances in the safety and execution of spine surgery has significantly changed the prognosis of these patients. Magnetic resonance imaging allows the diagnosis of a tuberculous lesion, with a sensitivity of 100% and specificity of 88%, well before deformity develops. Neurological deficit and deformity are the worst complications of spinal TB and are now detected much earlier than before. However, the present-day physicians are faced with newer problems of TB such as atypical clinical presentations, changing patient profile from lower strata to the higher social class, drug resistance, and the combination of HIV with TB infection. Surgeons should be aware of these pitfalls and provide the best care to the affected individual. It is important to reiterate that TB of the spine without complications is a medical disease and surgery is required to prevent and treat complications of deformity progression or neurological deficit. Panvertebral lesions, therapeutically refractory disease, risk or presence of severe deformity, a severe or progressively worsening neurological deficit, and lack of improvement or deterioration despite adequate chemotherapy are indications for surgery.

INTRODUCTION

Complications are an inherent aspect of surgery. Adverse events such as wound infection, instrumentation failure, and pseudarthrosis are frequently encountered by spine surgeons and are replete in the literature. However, medical complications, although widely prevalent in the surgical patient, are frequently beyond the spine surgeon's expertise and far less reported.

Medical comorbidities have substantial influences on the spinal surgeon's decision making as well as on the patient's clinical result. As the population continues to age, more and more elderly patients will be presenting for the evaluation of spinal pathology, as will the number of comorbidities affecting them.^{1,2} In patients >65 years of age, lumbar spinal stenosis is the most common indication for spine surgery.² Several studies have demonstrated that, in this patient cohort, comorbidities such as cardiovascular disease, lower extremity arthritis, and self-reported poor health are powerful predictors of inferior surgical outcome and increased complication rates in those undergoing decompression procedures.^{1,3,4}

According to *Taber's Cyclopedic Medical Dictionary*, a complication is "an added difficulty; a complex state; a disease or accident superimposed on another without being specifically related, yet affecting or modifying the prognosis of the original disease."⁵ Whereas surgical complications are ones that can be directly attributable to the operative procedure, medical complications in the surgical

patient are those that cause an increased burden on the patient's health yet are not caused directly by the operation. Having an understanding of common comorbidities that afflict the adult spinal patient is critical in order to maximize the chance of a successful operation while mitigating the risk of morbidity and mortality in the perioperative period. This chapter will discuss the prevention, diagnosis, and initial management of several of the most frequent medical complications in the adult spinal patient.

PULMONARY COMPLICATIONS

At 13%, pulmonary complications are the most frequently encountered medical issues following spine surgery and are associated with a 10-fold increased risk of death within 2 years.⁶ Both patient and surgical factors such as age, comorbidities, smoking history, increasing surgical invasiveness, and transthoracic approaches all significantly increase the risk of pulmonary complications and should be addressed and discussed with the patient preoperatively.^{6,7}

Pneumonia, which occurs in roughly 5% of all spinal surgery patients, has been reported as the leading cause of major medical complications in patients age 65 and older and is responsible for the majority of pulmonary complications.^{6,8} The clinical diagnosis is made in the patient with fever, productive cough, dyspnea, leukocytosis, and consolidation on chest X-ray and is confirmed with Gram stain and sputum culture. Nosocomial pneumonia is frequently the cause in postoperative patients and the predominant

pathogens include gram-negative bacilli and *Staphylococcus aureus*.⁹ Empiric antibiotics can be initiated once a specimen is obtained and tailored appropriately as organisms are identified.

Risk factors for postoperative nosocomial pneumonia include age > 70, pulmonary disease, smoking history, malnutrition, increased duration of surgery, thoracic/anterior approaches, and immobilization.¹⁰ As such, smoking cessation and nutritional optimization should be discussed with the patient well before the operation. Postoperatively, adequate analgesia is paramount to reduce chest splinting and promote aggressive pulmonary toilet. Early and frequent mobilization and physiotherapy focused on deep breathing are other important prophylactic measures.

Although less common, acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) is a continuum of a more severe pulmonary complication. Occurring after 1.3% of spine surgeries, this condition is characterized by an acute onset of severe hypoxemia recalcitrant to oxygen therapy with bilateral pulmonary infiltrates.⁶ Noncardiogenic pulmonary edema leads to diffuse alveolar damage secondary to etiologies such as pneumonia, sepsis, shock, trauma, and transfusion-related acute lung injury (TRALI).¹¹ The distinction between ALI and ARDS is strictly based on a P_aO_2/F_iO_2 ratio of ≤ 300 mm Hg and ≤ 200 mm Hg, respectively; however, clinically, patients with ARDS are much more in extremis.¹² Although multiple treatment strategies have been proposed, management is primarily supportive via mechanical ventilation.¹³

Among adult patients undergoing spine surgery, those having reconstructive procedures for deformity have substantial risks for developing ALI and respiratory failure. Urban et al. revealed that 8 of 55 patients (14.5%) who underwent sequential anterior-posterior deformity correction developed noncardiogenic pulmonary edema and elevated pulmonary vascular resistance.¹⁴ In a subsequent study using bronchoalveolar lavage (BAL) during spinal deformity surgery, the authors demonstrated significant increases in inflammatory cells and cytokines interleukin-6 and tumor necrosis factor alpha that correlated positively with ventilatory requirement. There was also a significant correlation between the number of inflammatory cells, namely lipid-laden macrophages, in the BAL and the number of vertebral segments fused.¹⁵ These data suggest that increasing invasiveness as seen in deformity surgery may lead to a showering of the pulmonary vasculature with inflammatory mediators that promotes microvascular permeability responsible for diffuse alveolar injury and

subsequent respiratory failure. As such, those undergoing complex, multilevel spine surgery must be monitored closely for any evidence of respiratory compromise.

CARDIAC COMPLICATIONS

Among the most serious adverse medical events that can occur in the perioperative period, cardiac complications are associated with substantial morbidity and mortality. According to a retrospective analysis of 1,591 patients, those with cardiac complications following spine surgery had a greater than fourfold increased risk of death within 2 years of the operation. This study also identified an overall 8.4% incidence of cardiac complications, with arrhythmia and myocardial infarction (MI) or ischemia being among the most common at 3% and 1.45%, respectively.⁶ Significant risk factors for cardiac complications included age > 65, congestive heart failure, positive cardiac and/or syncopal history, and increasing surgical invasiveness.^{6,16} These findings are consistent with those of Fujita et al, who demonstrated a 1.8% incidence of postoperative chest pain with electrocardiogram (EKG) abnormalities in 169 patients with an average age of 69.2 years undergoing multilevel thoracolumbar spine fusions.¹⁷ Similarly, in a retrospective review of posterior lumbar decompression and fusion in patients 65 and older, 3% of patients suffered a MI in the perioperative period.⁸

Myocardial infarction should be high on the differential diagnosis in the postoperative elderly spinal patient with chest pain; however, other etiologies should also be considered including pulmonary embolism (PE), pneumonia, or esophageal reflux. Evaluation for a cardiac source must be thoroughly pursued starting with a physical exam, assessment of vital signs and end-organ perfusion, as well as cardiopulmonary auscultation where crackles or a new murmur may be detected. An EKG should be performed immediately and compared to prior tracings, if available. ST segment depression with or without T-wave abnormalities may be present, indicating myocardial ischemia. Troponin levels should be obtained at symptom onset, 6 and 12 hours thereafter, as this cardiac biomarker may not be detectable until 4 hours after myocardial injury.¹⁸ Other studies such as chest X-ray, hemoglobin levels, or PE workup may be required as the clinical picture dictates. Cardiology consultation should be immediately obtained for management should there be evidence of myocardial ischemia or in the presence of high clinical suspicion.

The best treatment approach, however, is prevention. This begins in the office by identifying from history, symptoms, or medical conditions that may increase the patient's

risk of a perioperative cardiac event. Age >70, history of cardiac disease, diabetes mellitus, renal failure, angina, and poor functional status are a few of the clinical markers that warrant further investigation.¹⁹ Subsequent evaluation by the patient's primary care physician or cardiologist should be sought for medical optimization, risk stratification, and perioperative recommendations. One algorithm commonly used for preoperative cardiovascular evaluation for nonemergent surgery outlined by the American College of Cardiology/American Heart Association (ACC/AHA), stratifies risk based on the above clinical markers, functional capacity (e.g. ability to perform only ADLs versus sports activities), and risk level of surgery.¹⁹ This approach helps guide which patients may require further cardiac evaluation or intervention prior to proceeding to the operating room.

Once the decision has been made for surgical treatment, several steps can be taken to further mitigate the risk of a cardiac complication. Perioperative beta blockade may be used when clinically indicated which has shown to decrease the risk of cardiac death and MI by as much as 65–90%.^{20–22} Patients with impaired cardiac function may be placed further at risk due to the hemodynamic effects of prone positioning. Immediately preoperatively, adequate fluid replacement prior to induction of anesthesia minimizes these perturbations.²³ Furthermore, using transesophageal echocardiography, Dharmavaram et al. demonstrated that the use of a Jackson spine table or longitudinal bolsters, which allows the abdomen to hang free with the legs at heart level, permits adequate venous return and has the least effect on cardiac index.²⁴ Therefore, from the office to the operating room, utilizing these strategies and employing a multidisciplinary approach will decrease the patient's risk of perioperative cardiac complications.

■ VENOUS THROMBOEMBOLISM

Surgeons face the issue of venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and PE, with every operation performed. A decision must be made on the form of prophylaxis and consideration to the type of treatment should a VTE occur. While pharmacologic prophylaxis may be complicated by wound hemorrhage and bleeding complications, such problems near the spine can have devastating sequelae.²⁵ As such, it is critical to consider the risks and benefits prior to initiation of pharmacologic VTE prophylaxis.

When deciding who should receive chemoprophylaxis, one must consider the underlying mechanism of clot formation, patient risk factors, and the type of surgery

performed. Rudolph Virchow described a triad of features that precipitate VTE: endothelial injury, venous stasis, and hypercoagulability.²⁶ Surgical dissection inevitably causes endothelial injury, especially with great vessel retraction during anterior procedures, which stimulates the coagulation cascade. Venous stasis occurs both intraoperatively during positioning and postoperatively due to bed rest and relative immobility. The final component of the triad, hypercoagulable states, encompasses both inherited and acquired disorders that predispose a patient to clot formation. The most common genetic susceptibilities for venous thrombosis are factor V Leiden and prothrombin mutations, with a 4% and 2% prevalence, respectively. Others include deficiencies in protein C, protein S, or antithrombin III. Malignancy, hormone replacement, oral contraceptives, and nephrotic syndrome are a few of the acquired hypercoagulable states.²⁷

Elective operations generally pose the lowest threat of VTE in spine surgery. Using only pneumatic compression stockings and duplex ultrasound screening, Epstein demonstrated a 2.8% DVT rate following lumbar laminectomy and instrumented fusion and a 1% VTE rate after single-level anterior cervical fusion.^{28,29} As surgical invasiveness increases, however, so does the risk of thromboembolic events. In a retrospective review of 361 adult patients undergoing spinal deformity surgery, a 2.4% PE rate was observed despite pharmacologic prophylaxis. Furthermore, patients who had an anterior approach were at significantly higher risk than posterior surgery.³⁰ A meta-analysis of 14 studies with a total of 4,383 patients reiterates the exceedingly low number of thromboembolic events following elective spine surgery. In the absence of any form of prophylaxis, DVT and PE were seen at rates of 5.8 and 0%, respectively. Using only intermittent pneumatic compression (IPC), rates occurred at 1.8 and 0.4%, respectively. When mechanical and pharmacologic prophylaxis (in the form of aspirin, low-molecular weight heparin, or warfarin) were combined, rates were <0.0001 and 0%. However, the latter group experienced eight epidural hematomas requiring surgical evacuation.³¹

Spinal cord injury (SCI) patients lie on the opposite end of the spectrum with regard to VTE risk. DVT occurs in >80% of these patients if no prophylaxis is utilized as opposed to a range of 8.5% to 21.7% with the use of pharmacologic agents.^{32–35} Furthermore, paraplegics actually have significantly higher rates of VTE than quadriplegics, supposedly due to the flaccid paralysis and increased venous stasis as opposed to spasticity seen in higher-level injuries.^{36,37}

Figs. 124.1A and B: (A) A central pulmonary embolism (PE) or “saddle embolus” (arrow) is more likely to be symptomatic, have a coexisting deep vein thrombosis, and carries a substantial risk of PE-related death. (B) A subsegmental PE (arrow) is incidentally detected 63% of the time and has a significantly lower risk of PE-related death.

The American College of Chest Physicians (ACCP) guidelines for VTE prophylaxis recommend IPC, unfractionated heparin, or low molecular weight heparin for most patients undergoing spinal surgery.³⁹ Similarly, a systematic review by Glotzbecker et al. concluded that, given the low incidence of VTE following routine spine surgery, compression stockings with IPC should be the primary form of prophylaxis.³⁸ For high-risk patients, especially those with malignancy, an anterior-posterior approach, SCI, or surgery for spinal trauma, the ACCP recommends a combination of mechanical and pharmacologic prophylaxis. The chest guidelines acknowledge that the risk of major bleeding such as mass effect on the neural elements with neurologic deficit is likely <0.5% but is a potentially devastating complication.³⁹ As such, when selecting a method of anticoagulation, it is prudent to evaluate the entire clinical situation such as patient risk factors, extent of surgery, approach, and adequacy of hemostasis prior to chemoprophylaxis with close monitoring for any evidence of epidural hematoma if administered.

Signs and symptoms of DVT include calf pain, lower extremity edema, warmth, erythema, or Homan's sign; however, the physical exam is notoriously unreliable.⁴⁰ Laboratory evaluation, such as D-dimer level (which behaves like an acute-phase reactant), is also unreliable postoperatively as these values will be elevated in postsurgical patients. Although contrast venography is considered the gold standard diagnostic study, the best initial test is compression ultrasonography. With a sensitivity and specificity of 97–100% and 98–99%, this noninvasive test will

accurately detect the vast majority of clinically relevant deep vein thromboses.^{41,42} Similarly, many patients with PE do not exhibit hemoptysis, pleuritic chest pain, or circulatory collapse. Frequently, dyspnea and unexplained tachycardia are all that may be necessary to initiate a workup.⁴³ Spiral computed tomography angiography (CTA) has become the imaging study of choice for diagnosing pulmonary emboli. When compared to ventilation-perfusion scanning, CTA is able to identify other potential pathology and directly visualize the size and location of the emboli, including smaller, previously undetectable clots.^{44,45} This increased diagnostic ability must be considered prior to initiation of treatment, however, as the clinical relevance of these smaller PEs is unknown.⁴⁶

There are no established guidelines for the treatment of VTE after spine surgery. Management options, such as therapeutic anticoagulation or IVC filter placement, should be considered on a case-by-case basis. Important factors to consider include symptomatology, DVT location, and PE size. For example, symptomatic proximal DVTs account for >90% of acute pulmonary emboli and have a significantly higher mortality rate than those occurring below the knee.^{47,48} As for pulmonary emboli, large, central PEs are usually symptomatic with increased mortality risk, whereas small, subsegmental clots are often detected incidentally (Figs. 124.1A and B).⁴⁹ Finally, the benefits of treatment must be weighed against the risk of increased bleeding with potential for wound hematoma and/or paralysis.²⁵

DELIRIUM

Although neurologic deficits as a direct result of surgery are among the most worrisome following spinal procedures, medical causes are responsible for the majority of neurologic disturbances.⁵⁰ Delirium, an acute state of confusion, disorientation, and inattention with a waxing/waning course, is the most common neurologic complication.^{6,51-53} Elderly patients with poorer general physical condition are predisposed to developing delirium in the perioperative period. Pain, decreased mobility, psychological and physical stresses during hospitalization are frequently sufficient to precipitate postoperative delirium in a patient with an already decreased physiologic reserve.^{52,54} For example, up to 61% of elderly patients treated for femoral neck fractures develop delirium.⁵⁵ Although not as prevalent in spine surgery, mental status changes affect a substantial number of older patients. In a retrospective review to determine the incidence occurring specifically in postoperative spine patients, 13 of 341 patients (3.8%) developed delirium. All of these cases were in patients over 70 years of age, thereby representing an incidence of 12.5% in the elderly spine population in this study, which is consistent with other reports.^{8,50,56} Significant risk factors include preoperative dependence upon a wheelchair, greater number of preoperative oral medications (6.8 vs. 4.8), lower hemoglobin levels on postoperative day one (10 vs. 10.8 g/dL), emergency oncologic surgery, and primary spine infections.^{50,56} Delirium not only complicates the patient's postoperative course but leads to prolonged hospitalization and increased cost.^{55,57} Therefore, it is essential to identify patients at risk and be capable of efficiently managing this medical complication frequently encountered in the adult spinal patient.

The *Diagnostic and Statistical Manual of Mental Disorders* provides criteria that aid the clinician in the establishment of the diagnosis as well as differentiation from the gradual decline in cognitive function characterized by dementia. The four features include (1) a disturbance of consciousness with reduced ability to focus, sustain, or shift attention; (2) a change in cognition (memory, language, or orientation) or development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia; (3) development of the disturbance over a short period of time and fluctuation of symptoms during the course of a day; and (4) evidence from the history, physical examination, or laboratory findings that the disturbance is caused by direct physiologic consequences of a general medical condition.⁵⁸

Table 124.1: Deliriums.

<i>Causes of delirium</i>	<i>Examples</i>
D Drugs	Anticholinergics, antihistamines, benzodiazepines, opiates
E Eyes/Ears	Vision impairment, sensory deficits
L Low oxygen states	Myocardial infarction, pulmonary embolism, CVA
I Infection	UTI, surgical wound infection, sepsis
R Retention	Constipation, urinary retention
I Ictal state	Postseizure
U Underhydration	Dehydration
M Metabolic	Electrolyte and glucose abnormalities
S Subdural, Sleep deprivation	Intracranial hemorrhage

(CVA: Cerebrovascular accident; UTI: Urinary tract infection).

Once this acute confusional state has been recognized, identification of the etiology is paramount in order to provide quick and efficient treatment. Common culprits include medications and infections; however, various hypoxic and metabolic states may be responsible. A frequently taught mnemonic, *DELIRIUMS* (Table 124.1), is helpful in developing a differential diagnosis that can subsequently be used for directing management.⁵⁹

After assessment of vital signs and physical exam, appropriate labs and tests based on clinical suspicion may elucidate the source. Several initial steps may help resolve the delirium. For example, supplemental oxygen may acutely address causes of hypoxia; however, the underlying cause (e.g. postoperative anemia, MI) must be addressed. Medications known to precipitate mental status changes in the elderly such as anticholinergics and antihistamines should be discontinued and opioid analgesics minimized, if it all possible.⁶⁰ Metabolic causes, frequently sodium and glucose abnormalities, should be corrected and infectious etiologies (e.g. UTI, surgical wound) appropriately investigated and treated. If no source can be identified and the patient demonstrates continued symptoms and extreme agitation despite reorientation and correction of possible etiologies, small doses of sedatives such as haloperidol can be judiciously administered. Such pharmacologic treatment must be given cautiously, however, as these drugs can potentially prolong delirium in some patients.^{54,61}

Alcohol withdrawal should also be considered in the elderly patient with altered mental status. Signs and symptoms, beginning within 1–2 days of abstinence, include

hypertension, tachycardia, insomnia, and tremulousness. Delirium tremens, the most severe and dangerous form of alcohol withdrawal occurring after 4–5 days of abstinence, is characterized by hallucinations, severe autonomic instability, and seizures.⁶² Benzodiazepines and intensive care unit monitoring are often necessary in the management of this condition. Preoperative screening may help detect patients at high risk for alcohol withdrawal and appropriate prophylaxis with thiamine, folate, and benzodiazepines can be instituted.^{63,64}

CONCLUSION

Operative technique is only one component of a good surgical outcome. Multiple factors come into play when deciding on surgical intervention and when counseling a patient on an upcoming operation. The surgeon must be aware of and discuss with the patient that an increasing number of comorbidities may minimize potential therapeutic effects while simultaneously increasing the risk of perioperative complications. Especially in the elderly population, pneumonia, MI, thrombotic events, and delirium may seriously impair a patient's recovery and substantially increase morbidity and mortality. Therefore, it is imperative to identify patients at risk for poor surgical outcome or adverse medical events, and through a multidisciplinary approach, work to optimize the patient's health and efficiently treat perioperative complications in order to maximize the potential for a successful operation.

KEY POINTS

- Lumbar decompression for spinal stenosis is the most common operation for elderly patients undergoing spine surgery. Those with more comorbidities, especially cardiovascular disease, lower extremity arthritis, depression, and poor self-rated health have significantly worse outcomes than their healthy counterparts. These patients must be thoroughly counseled on surgical expectations and attempts made at medical optimization prior to surgical intervention.
- Older age and elevated surgical “invasiveness,” a function of the extent of decompression and instrumentation over a given number of spinal levels, significantly increase the risk of medical complications of nearly every organ system.
- Due to the relatively low risk of VTE in elective spine surgery, compressive stockings with IPC devices will

usually suffice for postoperative VTE prophylaxis. The addition of chemoprophylaxis should be considered for high-risk patients such as complex deformity operations, anterior approaches, spinal trauma and SCI patients, and those with malignancy or other hypercoagulable states. Patients receiving pharmacologic prophylaxis must be monitored closely for any signs or symptoms of epidural hematoma, which requires urgent evacuation.

- Postoperative pulmonary and cardiac complications increase risk of death >10- and fourfold within 2 years of surgery, respectively. As pneumonia and myocardial ischemia/infarction are among the commonest medical complications following spine surgery in the elderly patient, every effort must be made to identify those at risk and take appropriate measures to prevent such events.
- Above all, physicians must first “do no harm.” Any operation places the patient at substantial risk, both surgical and medical. Age, comorbidities, and extent of surgery must be contemplated prior to any elective operation. If the risk-to-benefit ratio is favorable for surgery, medical optimization with the assistance of other specialties should be sought out as indicated.

- This retrospective analysis of 1,591 patients describes the incidences and risk factors for medical complications after

spine surgery based on organ system. Age greater than 65 and increasing surgical invasiveness were significant risk factors for complications in five of the six organ systems evaluated.

Carreon LY, Puno RM, Dimar JR, et al. Perioperative complications of posterior lumbar decompression and arthrodesis in older adults. *J Bone Joint Surg Am.* 2003;85:2089-92.

The authors report the complication rates in patients age 65 years and older undergoing the most common surgical procedure in the adult spine population. 21% of patients had at least one major complication and 70% had at least one minor complication. Risk factors for developing a complication were increasing age and number of fused spinal levels.

Glottzbecker MP, Bono CM, Wood DK, et al. Thromboembolic disease in spinal surgery: a systematic review. *Spine (Phila Pa 1976).* 2009;34:291-303.

This literature review demonstrates the low rate of VTE and recommends that compressive stockings with intermittent pneumatic compression devices are usually sufficient for prophylaxis following most routine spine surgeries. The authors suggest that patients with increased VTE risks such as malignancy, prior VTE, neurologic deficit, or anterior approach should be considered for additional chemoprophylaxis or IVC filter placement.

Baron EM, Albert TJ. Medical complications of surgical treatment of adult spinal deformity and how to avoid them. *Spine (Phila Pa 1976).* 2006;31:S106-18.

This review article highlights the presentation, treatment, and prevention of medical complications that occur specifically following spinal deformity surgery. As these patients have among the highest risks of medical complications, many of the concepts discussed in this article can be applied to the general spine population.

Management of Cerebral Spinal Fluid Leaks

INTRODUCTION

Disruption of the thecal sac is a relatively common occurrence in spinal surgery and may result from traumatic or iatrogenic injury causing a cerebrospinal fluid (CSF) leak. Durotomies can occur anywhere along the spinal column during surgery with a reported 3.1–3.84% incidence.^{1–3} Traumatic injuries such as burst and lamina fractures can also result in lacerations of the dura and are commonly associated with neurologic deficit.^{4–7} Most spinal surgeons will encounter dural tears (Fig. 125.1) during the course of their careers and therefore it is important to understand how to prevent them and, if present, manage them effectively.

EPIDEMIOLOGY

Traumatic

Traumatic dural injuries typically result as a laceration from an associated fracture in the vertebral body or lamina. In thoracolumbar and lumbar burst fractures, several studies have shown intraoperative findings of traumatic dural tears ranging from 10% to 19% occurring both anteriorly and posteriorly.^{4–6,8} Anterior dural lacerations were found in 10% of patients treated with anterior decompression. These tears were typically vertically oriented and likely a result of an asymmetrically retropulsed bone fragment as seen on preoperative computed tomography (CT) and were associated with a neurologic deficit.⁸

Fig. 125.1: Incidental dural tear with arachnoid membrane intact.

Posterior dural lacerations occurred as a result of lamina fractures in up to 19% of operatively treated patients, and of those patients, 36% were found to have neural elements entrapped between the fragments.^{5,6} Using current imaging techniques, it is difficult to identify lamina fractures with nerve root entrapment.⁵ The presence of a burst fracture, lamina fracture, and neurological deficit was highly predictive of a dural laceration.⁶

Iatrogenic

Iatrogenic dural injuries are one of the most common complications in spinal surgery and its rates vary widely

Fig. 125.2: Ossified posterior longitudinal ligament (OPLL). Patients with OPLL have the highest risk factor for incidental durotomies during anterior cervical procedures.

in the literature with reported rates of 1–17%.^{1,9–14} At one academic institution, a retrospective review of 3,000 elective spine surgery cases over a 15 years period revealed a 3.5% incidence of incidental durotomies with 1.3% in cervical, 6.6% in thoracic, and 5.9% in lumbar procedures. In addition, it was found that there was a 3.1% incidence in primary and 6.5% incidence in revision surgeries.³ Khan et al. also reviewed over 3,100 consecutive degenerative lumbar spine surgeries and found a 7.6% rate in primary versus 15.9% in revision cases.¹⁰

Several risk factors and mechanisms are associated with a dural tear and subsequent CSF leak. Revision surgery was the strongest risk factor (2.21 times more likely) for a dural tear while others include age (> 65), degenerative diagnosis, lumbar surgery, and surgical invasiveness (more levels and/or instrumentation).¹⁵ Scar tissue obfuscates the normal anatomy during dissection in revision cases, while in the elderly, the dura has been observed to be more fragile and thin. Surgeons tend to manipulate the dura more during lumbar surgery and especially so when operating on increasing number of levels, which therefore increases the risk of CSF leak. The risk of iatrogenic durotomy also increased for the surgical treatment across the spectrum of degenerative diagnosis—disc herniation (4%), stenosis (8%), and spondylolisthesis (11%).^{16–18}

In cervical spine procedures, the incidence of an iatrogenic durotomy was 1% with the highest risk in patients with an ossified posterior longitudinal ligament (OPLL) (Fig. 125.2) and second, in revision anterior cervical surgeries (anterior approach through prior incision).¹⁹ Other

reported risk factors for iatrogenic injury include limited surgical experience and improper technique.^{15,20,21}

The most common mechanisms of injury are direct trauma or lacerations during surgery. Factors involved include dissection of adherent tissue (ossification of the ligamentum flavum, fibrosis or scarring), lacerations from bony spikes during decompression maneuvers or from incorrect screw placement, or uncovering eroded dura.^{22,23} The primary surgical instrument involved in dural lacerations is the Kerrison rongeur as it is the most commonly used tool during lumbar decompression procedures.²¹

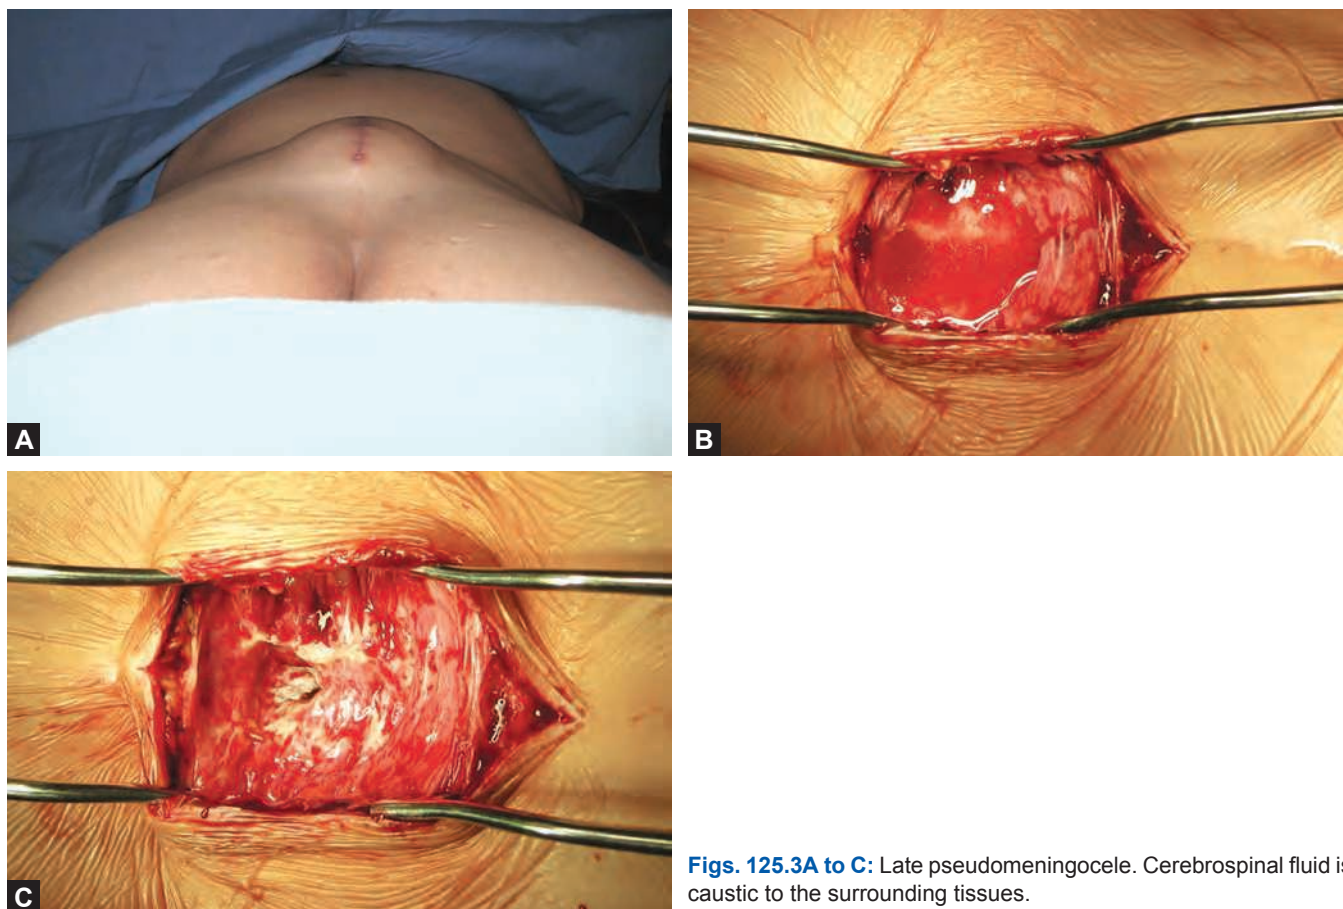

CLINICAL DIAGNOSIS

During the intraoperative setting, there may be direct visualization of the CSF leak through a dural tear. Indirect clues of a durotomy are the collapse of the thecal sac, pulsatile clear fluid in the field, or a sudden increase in epidural bleeding. Incomplete tears leaving the arachnoid membrane intact may result in no CSF leak intraoperatively but then burst open due to increased intra-abdominal pressure postoperatively.²²

In the postoperative setting, diagnosis of a CSF leak may be more difficult but signs include patients with a postural headache, nausea, emesis, dizziness, and/or persistent serous or clear wound drainage. A CSF fistula may form within the first week of surgery. Evaluation for β -2 transferrin in the drainage, which is both sensitive and specific for CSF, can confirm the diagnosis.^{24–26} Dural tears presenting beyond 7 days postoperatively are uncommon (0.28%) and may be seen as a pseudomeningocele (Figs. 125.3A to C), an encapsulated extravasation of CSF fluid into the soft tissues.^{1,27} Pseudomeningoceles can develop at any time postoperatively and may first be noticed as an underlying fluctuant mass near the surgical site. Magnetic resonance imaging (Figs. 125.4A and B) or a CT myelogram can help confirm the presence of a CSF leak and the filling of a pseudomeningocele.²⁷

TREATMENT

Ideally, prevention of dural tears is the most effective strategy by planning appropriately and using good surgical technique, but if an incidental durotomy occurs, primary watertight repair is the mainstay of treatment.^{9,11,13} To ensure optimal treatment, proper visualization is required to fully expose the dural tear. This may include appropriate hemostasis or further resection of bone and soft tissue. Once the edges are identified, suture repair is done in a

Figs. 125.4A and B: Magnetic resonance imaging T2 images demonstrating persistent cerebrospinal fluid leak with filling of a pseudomeningocele.

Figs. 125.5A and B: Watertight primary repair.

Figs. 125.6A and B: Primary repair before and after fibrin glue placement.

number of ways including running locked, simple running, or simple interrupted techniques. Size and type of sutures used vary from 4-0 to 5-0 silk, Prolene (Ethicon, Somerville, NJ), or Gore-tex (W.L. Gore, Flagstaff, AZ). Watertight repair (Figs. 125.5A and B) is essential and can be tested by increasing the intrathecal pressure using a Valsalva maneuver by the anesthesiologist. In the event that there is a persistent leak or the dural edges cannot be closed due to significant tension, a patch graft has been used. Due to the impermeability of fat and its lack of adherence to neural elements, these grafts have been used to plug dural defects with good effect.^{28,29} Other patch grafts used are muscle and fascia.^{1,13} Some authors advocate adjunct use of tissue sealants such as collagen matrix, fibrin glue, and hydrogel in addition to suture repair (Figs. 125.6A and B).³⁰⁻³³ Collagen

matrix has been used as an only graft in both primary and secondary means of closing the dura without any increased risk of complications and is replaced by natural collagen after 3 months.³¹⁻³³ The use of subfascial drains for bleeding with concomitant CSF leak is controversial but has been shown recently not to cause any increased adverse effects including formation of spinal cutaneous fistulas.^{10,13} In fact, one study showed successful healing of the dura despite a persistent CSF leak from the repair with prolonged drainage using a subfascial drain that helped prevent formation of a pseudomeningocele.³⁴ A tight layered closure especially the fascia helps to prevent egress of CSF that can slow wound healing and form fistulas or pseudomeningoceles possibly resulting in meningitis or neural injury.²² Primary repair of dural tears in the anterior cervical

Figs. 125.7A and B: Subarachnoid lumbar drain typically placed between L2 and L3. Typically titrated to equilibrate intra- and extrathecal pressure up to 360 mL/day depending upon symptoms.

spine may be difficult. Smaller tears have been covered with Gelfoam (Pfizer, New York, New York) or a collagen matrix, while larger tears are treated with subarachnoid drainage (Figs. 125.7A and B) either at the time of the index procedure or up to a week after for persistent leaks.^{19,31}

Postoperatively, the recommendation for bed rest varies from only in symptomatic patients to standard protocols of 1–3 days.^{13,35} Even with successful repair, patients may continue to exhibit symptoms due to decreased intracranial CSF for several days. Patient positioning depends upon location of the dural tear to reduce pressure along the repair.³⁶ Patients with cervical CSF leaks are positioned upright and those with thoracic or lumbar durotomies are placed flat. Indications of a successful repair include the lack or resolution of symptoms such as postural headache, nausea, dizziness as well as absence of clear drainage from the wound or the subfascial drain. Persistent CSF leak despite repair can be treated with compression such as abdominal binders as well as closed subarachnoid drainage titrated up to 360 mL/day depending on symptoms to equilibrate the CSF pressure between the intra- and extradural space with up to 92% resolution within 5 days.^{11,37} Other conservative treatment strategies for persistent CSF fistulas/leaks have included epidural blood patches and percutaneous fibrin sealant with varying degrees of success.^{38–40} Prompt surgical repair of the dura should be done in cases where conservative management has failed, neurologic symptoms develop, or the CSF leaks excessively.

Our Treatment Strategies for a Lumbar Dural Tear

1. Identify dural tear intraoperatively
2. Obtain appropriate exposure of the tear by resecting bone and soft-tissue as needed as well as maintaining hemostasis
3. Place a cottonoid pledget over the tear to prevent inadvertent injury to the nerve rootlets during exposure maneuvers and to maintain dural turgor
4. Ensure extruded nerve rootlets are gently placed back within the dura prior to repair
5. Perform a figure-of-8 repair of small defects and a running-locked suture repair of large defects using 5–0 Gore-Tex
6. Ask anesthesia to initiate a Valsalva maneuver to check for any leaks
7. If repair is watertight, no further action is needed but if there is still a small leak then use DuraGen as an adjunct
8. In the case of a tenuous repair, suture localized fat graft into position as a patch
9. Place a subfascial drain initially to suction then switch to gravity the morning after surgery, and finally discontinue on the third postoperative day
10. Perform a watertight closure of the fascial and skin layers
11. Give anti-emetics postoperatively to avoid increased intrathecal pressure associated with emesis
12. Keep supine in bed rest for 24 hours
13. Elevate head of bed at 30° for 8 hours. If asymptomatic, trial ambulation with assistance
14. Restart postoperative protocol if patient becomes symptomatic
15. If after 72 hours, the patient remains symptomatic and/or there is persistent clear wound drainage, explore the wound in the operating room with possible placement of a subfascial versus a subarachnoid drain
16. Re-start postoperative protocol as above.

Management of Dural Tears in the Cervical Spine Differ in the Following Ways

1. Repair directly, if amenable
2. If not repairable, especially common after anterior cervical discectomy procedures, place Gelfoam over the defect and consider lumbar subarachnoid shunt (observation only usually sufficient)

3. Place submuscular (anterior approach) or subfascial (posterior approach) drain to gravity. Discontinue anterior drain on postoperative day 1 or 2 and the posterior drain on day 2
4. Keep head of bed elevated at 30° overnight. If asymptomatic, trial ambulation with assistance
5. If after 72 hours, the patient remains symptomatic and/or there is persistent clear wound drainage, consider placement of a lumbar subarachnoid shunt.

OUTCOMES

Persistent CSF leaks from dural tears intraoperatively may result in loss of thecal sac hydrostatic pressure leading to poor visualization from epidural bleeding or expose nerve rootlets to injury. Surgical progress is slowed and exposes the patient to potential complications including neurologic symptoms (radicular, cauda equina), infection, subdural hematoma and hygroma and tonsillar herniation.⁴¹⁻⁴⁴ A feared complication, meningitis, occurs only 0.18% of the time.⁴⁵ Persistent CSF fistulas and formation of pseudomeningoceles increase the risk of complications such as meningitis, epidural abscess, wound healing delay or infection, arachnoiditis, and nerve root entrapment.⁴⁶⁻⁴⁹

Several studies have shown no long-term adverse effects from dural tears recognized and treated promptly and did not appear to increase the risk of neurologic injury, infection or arachnoiditis.^{1,13,14} An oft-cited study contrasts these results with a 10-year follow-up of patients with incidental durotomy after lumbar disc surgery that shows trends towards poorer outcomes including increased rates of back pain, headaches, and difficulty with daily activities though the reasons for this are not clearly understood.⁵⁰ From a medicolegal standpoint, incidental dural tears are the second-most common cause of malpractice lawsuits in spine surgery.⁵¹ It is therefore important to fully explain to patients preoperatively the incidence and potential risk of dural injuries, their signs and symptoms, and general treatment strategies. Though this may not obviate filing a malpractice suit, patients will at least be more informed participants in their surgical care.

SUMMARY

Dural tears may result from traumatic spinal pathology such as fractures or iatrogenic injuries during surgery. Incidental durotomies are one of the most common complications spine surgeons will face. Therefore, it is imperative to understand how to properly diagnose and treat dural

injuries. Prevention is the most important aspect with appropriate preoperative planning and meticulous surgical technique. Certain cases are at the higher risk of dural tears including revision procedures, cervical OPLL, elderly, and higher degrees of stenosis with associated spondylolisthesis. Effective treatment strategies begin with a watertight dural closure if amenable followed by adjunctive measures as needed and postoperative vigilance of signs and symptoms. Prompt recognition and treatment of dural injuries generally lead to good outcomes with no long-term negative consequences.

KEY POINTS

- The most common cause of CSF leaks is iatrogenic dural injury.
- Risk factors for intraoperative dural tears include revision procedures, increasing patient age, higher degree of spinal stenosis, and lack of appropriate surgical technique or experience.
- Most dural tears can be managed effectively with multiple intraoperative and postoperative techniques.
- Primary repair with watertight closure is the “gold standard.”
- Overall outcomes not affected when prompt diagnosis and treatment are initiated.

NEUROLOGIC INJURIES

Overview

Neurologic injuries can happen directly or indirectly: Direct causes are essentially mechanical: contusion, laceration, traction, compression, and thermal (cautery) damage to the nerves. Indirect causes include ischemia, compression, systemic hypotension, anemia, or poor oxygenation. Especially ischemia can lower the threshold for neural injury from mechanical etiologies and vice versa.

Central or peripheral neurologic recovery takes up to 12–18 months after the surgery. The spinal cord terminates at the L1–L2 level as the conus medullaris, which should be considered since it is less resistant to manipulation during surgeries around the level. Nerve root and peripheral nerve injury can result in varying degrees of pain, paresthesias, and weakness. Transient compression is more likely to affect sensory function, i.e. motor recovery tends to precede sensory recovery.

The lumbar sympathetic chain lies anterior to the psoas muscle and can be injured during retroperitoneal approaches to the lumbar spine manifesting as patient complaints of contralateral foot coolness. Preoperative investigation regarding anatomic anomalies is also important to avoid nerve injuries. Abnormal osseous anatomy (abnormal pedicle morphology, compressive osteophytes, ossified ligamentum flavum) can complicate the surgical

procedures. The superior hypogastric sympathetic plexus is at risk of injury during approaches to the L5–S1 disc space.^{1,2} Anterior injury can result in retrograde ejaculation, which misdirects the ejaculate into the bladder instead of through the urethra.³

To avoid and predict neural injuries, a variety of neuro-monitoring techniques are used to monitor neural conduction. The most common in current use for spinal surgery are somatosensory evoked potentials, transcranial electric motor evoked potentials, and electromyography.

Issues to be Concerned in Each Surgical Procedure

Decompression

Lateral margin of the nerve root (i.e. medial wall of the pedicle) should be identified. Nerve roots may be attenuated over a bulging disc and not recognized owing to their peculiar appearance placing them at injury risk. Forceful retraction of a nerve root lying within a stenotic neural foramen risks nerve root injury. After the decompression, nerve recovery may replace one symptom with another (e.g. pain in a given distribution may be replaced by paresthesia).

Discectomy

Large herniations with dorsal root displacement and anomalous nerve root anatomy (i.e. conjoined nerve roots

Fig. 126.1: The patient underwent lumbar decompression and instrumented fusion. The postoperative computed tomography showed a medial breach of the right L4 pedicle screw. The patient showed neither complaint nor neurodeficiency.

with inferior root displacement) can increase the risk of inadvertent injury. Upper lumbar disc herniations can pose a problem because obtaining adequate exposure is difficult due to the more narrow pars interarticularis and decreased tolerance for retraction of the thecal sac at these levels. Excessive retraction of nerve root or thecal sac risks neurologic injury and should be avoided.

Instrumentation

In the lumbosacral segment, the nerve roots lie along the inferomedial edge of the pedicle and are at risk of injury from medial and inferior pedicle breaches during pedicle screw placement. Intraoperatively consideration of anatomic landmarks, use of fluoroscopy, navigation system, and/or neuromonitoring techniques can be used to confirm appropriate placement. Pedicle screws should be directed such that they remain intraosseous to avoid critical adjacent neurovascular structures (Fig. 126.1).

Interbody Fusion Techniques

Neurologic injury can result from inappropriate graft placement or dislodgement, overly aggressive retraction in inserting the graft. Adequate exposure, gentle retraction to the degree necessary for safe implant placement, and careful discectomy technique help to minimize the risk of neurologic injury.

Durotomy Repair

Incidental durotomies can lead to neurologic complications if not handled properly. Dural injury is described in detail in the next section as well as a separate chapter in this textbook.

Bone Graft Harvest

Harvesting of anterior or posterior iliac crest can lead to some cutaneous nerve injuries,^{4,5} resulting in painful neuromas and meralgia paresthetica: Harvesting bone graft from anterior approach may damage the lateral femoral cutaneous nerve, which provides sensation to the anterolateral thigh. It may be damaged during dissection within 3 cm posterior of the anterior superior iliac spine, while a posterior approach to the iliac crest may damage the superior cluneal nerves that are involved in sensation of the buttock if dissected >6 cm lateral to the posterior superior iliac spine.

Deformity Correction

Surgical management of spinal deformity is associated with an increased risk of neurologic injury.⁶ Neuromonitoring can help providing a safer surgical environment. Anterior exposures may require ligation of multiple adjacent segmental vessels, which carries a theoretical risk of clinically significant spinal cord ischemia. In patients undergoing deformity correction, the risk is minimal provided ligations are performed unilaterally and on the convexity.⁷ In patients without deformity, ligation of segmentals bilaterally at three levels or less can be safely performed.⁸ Excessive correction can result in mechanical or ischemic injury from kinking of the vasculature and cauda equina. Furthermore, direct vertebral derotation techniques through pedicle screws can risk fracture of the pedicle.

Wrong-Level Surgery

Severe spondylolisthesis or spondylolysis sometimes misleads the surgeons to wrong-level surgeries, which may cause the failed back surgery syndrome being a severe, long-lasting, disabling and relatively frequent complications (5–10%), as well as neurologic injury (Figs. 126.2A to C).⁹ Wrong-level surgery would be avoided by confirmation of surgical information including presurgical images and

Figs. 126.2A to C: (A) Normal alignment leads the surgeon to the correct level. (B) In case with increased lumbar lordosis, decreased interlaminar and interspinous space sometimes make it hard to identify the correct level. (C) In case with spondylolytic spondylolisthesis, surgeon can misidentify the adjacent level as the correct one.

enough knowledge regarding the pathology. The advent of intraoperative computed tomography (CT) scan imaging with equipment such as the O-Arm (Medtronic) and with the concomitant use of navigation, wrong level surgery can be minimized.

One of the other causes for wrong surgery is lumbosacral transitional vertebra,¹⁰ which is a congenital vertebral anomaly of the L5–S1 junction in the spine (Fig. 126.3). Definite manifestations are lumbarization of S1 (nonfusion between the first two sacral segments) or sacralization of the fifth lumbar vertebra (fusion between L5 and the first sacral segment). About 6.6% prevalence of six-lumbar-

vertebrae patients has been reported. This alteration may contribute to incorrect identification of a vertebral segment.¹¹

DURAL INJURIES

Overview

Incidental durotomy is a relatively common complication. Most of the dural injuries occur in the lumbosacral region with average 3.5% (1–17%) incidence.^{12,13} Signs and symptoms of dural leak include headache, nausea, vomiting, and persistent drainage of clear fluid from wound.

Fig. 126.3: Radiographic classification system (Types IA-IV) of lumbosacral transitional vertebra based on Castellvi.¹⁰

Dural disruption may result in subsequent cerebrospinal fluid (CSF) drainage and sometimes major or minor neurological disorders. An incidental durotomy is an unintended, often unavoidable tear of the dura mater during lumbosacral surgery. Dural disruption and subsequent CSF leak often occur from direct trauma or laceration, and dural entry is much more common in revision procedures (3.5% for primary discectomy, 8.5% for spinal stenosis surgery, and 13.2% for revision discectomy procedures.¹⁴) This is due to adhesions in the epidural space, dural scarring, fibrosis, and loss of surgical landmarks. Also iatrogenic surgical dural injuries were reported to amount to approximately twice as frequent (15.9% vs. 7.6%) in revision degenerative lumbar spine surgery.¹⁵ Conditions that increase the risk of a dural injury during primary spinal procedures include eroded or thin dura, adhesions and fibrosis, or dural redundancy in patients with severe spinal stenosis.¹⁶ The most common instrument leading to durotomy is the Kerrison punch followed by the curette and then the drill. Kerrison bites injury is the most common in the lateral gutters especially in areas of critical lateral recess stenosis, and medial bites during the surgery.¹³ Excessive traction on severely herniated discs and anatomically incorrect screw placement have also been described as causative factors for dural laceration¹⁷ as well as lack of surgical expertise and improper technique.¹⁸ However, McMahon et al. reported that they do not regard the years of physician training or resident experience as a major risk of incidental durotomy: residents and fellows as a whole accounted for 75% of all durotomies; however, rest of the incidence is due to attending surgeons. This means that the years of physician training or resident experience do not appear to be a major determinant of the risk of incidental durotomy.

Diagnosis

Incidental durotomy should be promptly diagnosed and repaired during the surgery, which will be exposed by a CSF leak intra/postoperatively. Late-presenting dural tears are much less common, having a frequency of 0.28%.¹² Persistently, clear or serosanguineous wound drainage following spinal surgery may suggest a dural tear and CSF fistula formation. If the diagnosis is in question, laboratory evaluation through electrophoresis for β -2-transferrin is useful, which is a sensitive and specific test for the presence of CSF.^{19–21} Postoperative fluctuant mass over the surgical site implies pseudomeningocele, which is due to the direct

Figs. 126.4A and B: Sagittal T2-weighted magnetic resonance imaging (A) and early phase postmyelogram sagittal reconstructed computed tomography (B) of postoperative lumbar spine demonstrating early filling of pseudomeningocele (arrow).¹³

CSF extravasation into soft tissues with eventual development of a fibrous capsule (Figs. 126.4A and B),²² which sometimes causes localized nerve root entrapment or adhesions leading to radicular symptoms. Therefore, postural headaches combined with increased sciatic pain may suggest the presence of a pseudomeningocele.^{23–25} Despite the frequency of dural tears in spinal surgery, meningitis is a rare complication reported to occur with a frequency of 0.18%.²⁶ In the situation of a persistent CSF fistula, the risk of meningitis, epidural abscess, arachnoiditis, delay of wound healing, or wound infection are all significantly increased.^{17,27,28}

Dural Repair

Careful preoperative planning and meticulous surgical technique can prevent CSF leak, particularly in patients at high risk of dural tears such as those with surgical revisions and Spondylolisthesis.¹⁷ The optimal treatment of incidental durotomies remains primary repair: Adequate exposure of the tear and surrounding normal dura is necessary for the proper repair of a dural opening. Primary repair is typically obtained by 5-0 or 6-0 silk, Prolene, or Gore-Tex sutures. In addition to sutures, adjuvant use of collagen matrix, fibrin glue, and Dermabond can be helpful.^{29–31} For tears that cannot be closed without undue tension on the thecal sac, the use of a patch graft is recommended using fat, fascial, and muscle grafts.^{12,31,32} After the repair, a tight fascial closure with nonabsorbable suture material is of extreme importance.¹⁷

Fig. 126.5: The spectrum of vascular complications in spine surgery. A schematic diagram illustrating the spectrum of vascular injuries, complications, or sequelae associated with modern spine surgery, both anteriorly and posteriorly (or posterolaterally).³³

VASCULAR COMPLICATIONS

Overview

Vascular complication may arise directly from vascular injury or indirectly as a consequence of the injury (Fig. 126.5 and Table 126.1).³³ The most common vascular complication in spinal surgery is direct trauma to a vessel resulting in acute bleeding. Although venous lacerations are still most common, more arterial complications, especially occlusions and thrombosis, are being reported including deep vein thrombosis. Prevention of vascular complications is assisted by (1) knowledge of the vascular anatomy and common variants, (2) knowledge of the blood vessel and bone relationships, (3) gentle intraoperative techniques with appropriate illumination and magnification, and (4) preoperative planning.³³

Lumbar Vascular Complications

Figure 126.6A shows the general anatomy in the anterior exposure of the lumbosacral spine.³⁴ Anterior approach gives us different orientation for the vascularities. Regardless of the type of anterior exposure, access to the vertebral bodies and intervertebral discs will require identification, mobilization, control, ligation, and/or protection of the arteries and veins that cover the anterior lumbar spine.³³ Preoperative imaging using reconstructed 3-dimensional images can be helpful (Fig. 126.6B). In the lateral or antero-

Table 126.1: Reported vascular complications in spinal surgery.

- Direct injury (anterior surgery)
 - Abdominal aorta/Vena cava
 - Common iliac arteries/veins (direct injury, fistula, aneurysms, thrombosis)
 - Internal iliac arteries/veins
 - External iliac arteries/veins
 - Lumbar segmental arteries/veins
 - Iliac artery thrombosis (retraction related)
 - Iliolumbar vein (direct injury, especially the left)
- Lumbar discectomy/Posterior approach interbody fusion
 - Vena cava and iliac vein from rongeur during posterior surgery
 - Superior rectal artery
 - Inferior mesenteric artery
- Iliac graft harvest
 - Superior gluteal arteries (posterior surgery)
 - Deep iliac circumflex artery (aneurysm from anterior surgery)
- SMA syndrome
 - Superior mesenteric artery

lateral exposure of the lumbar spine is most appropriate for pathology at or above L3–L4. The side of exposure is most often dictated by the pathology, however, the left side is usually chosen if all else is equal owing to the resiliency of the aorta compared with the vena cava. Considering the lateral or flank exposure of the retroperitoneum, the psoas major can be relaxed by flexing the hip and knee,

Figs. 126.6A and B: Transabdominal view of the abdominal aorta and inferior vena cava: (A) The vertebral column is posterior to the vessels. The aorta lies to the left of the vena cava. (B) Three-dimensional image reconstructed from enhanced computed tomography images of metastatic vertebral tumor patient. Segmental vessels from aorta and vena cava going toward the tumor (green) are depicted.

rendering vascular dissection safer and easier. Incisions are placed according to the vertebral level of interest, and the approach is carried to the retroperitoneal space. The psoas major is the key landmark to guiding the deep dissection. Each segmental vessel is independently isolated over the concave vertebral body with a right angle hemostat and clipped or ligated. Double ligation or clipping is preferred toward the great vessels, leaving at least 1 cm of lumbar segmental vessel to prevent making a hole in the aorta or vena cava.

Ligation of the segmental vessels should be over the middle of the vertebral body. By staying away from posterior ligation of the segmental vessels, the risk of interference with foraminal or collateral blood flow is reduced. If the ligature, suture, or clip should tear or dislodge, the major vessel can develop a large perforation in its sidewall. In addition, it is technically easier to control the vessels in this anatomic location. Emphasized four key vascular components and considerations for anterior lumbar exposure are as follows: (1) the iliolumbar vein, (2) the left iliac vein, (3) the middle sacral vessels, and (4) the type of arterial retraction so as to optimize exposure but minimize the risk of altered blood flow or displaced plaque.³⁵ Exposure of LS-S1 is probably the easiest vascular window: Previous magnetic resonance angiography-based study found that 18% of their cases showed the ilio-cava bifurcation occurred at or below the L5-S1 intervertebral disc space.³⁶

Vascular injuries and complications during anterior lumbar exposures rarely result in serious sequelae unless

Figs. 126.7A to D: A 70-year-old woman who underwent correction surgery for deformity (A and B). After the surgery, she showed hypovolemic shock due to the massive hemorrhage in the retroperitoneal space (C: arrows). Emergent intravenous radiology proved that the hemorrhage was due to the active bleeding from a branch of lumbar artery (D: arrows), which was controlled by the embolism using intravenous treatment.

the injury results in total disruption of the vascular channels to the lower extremity or other important viscera.³⁷ Prompt recognition and repair remain the standard of care.

Insufficient hemostasis in anterior approach can lead to fatal bleeding and hematoma as the approach lacks the chances of compressed hemostasis as is in posterior approach (Figs. 126.7A to D).

Fig. 126.8: The segmental vessels arising off the aorta form radicular branches that then pass through the neuroforamina to form the anterior and posterior spinal arteries.

The segmental vessels arising off the aorta form radicular branches that then pass through the neuroforamina to form the anterior and posterior spinal arteries, which should be taken care of in posterior lumbar surgeries (Fig. 126.8).

INSTRUMENTATION COMPLICATIONS

Spinal instrumentation complications can occur as a result of one or more than one of the following occurrences:³⁸

Biologic Failure

Infections can occur shortly after implant insertion or many years after the surgical procedure, which can be related to the presence of the hardware itself, the increased operative time associated with the instrumentation procedure or systemic infection. The next section addresses infection in detail.

The bone-implant interface integrity relies on the quality of the host bone and/or vertebral endplate. Osteoporosis can lead to early fixation failure or implant loosening before an attempted arthrodesis procedure heals. Deficient vertebral endplates or subchondral osteoporosis can lead to interbody device loosening or subsidence.^{39–41}

Pseudarthrosis may occur in even the most technically well-performed operation in an ideal, young, healthy, non-smoking patient. It is sometimes difficult to identify the pseudarthrosis until its associated micromotion results in pedicle screw or rod breakage.

Many other patient-related factors contribute to biologic failure and subsequent instrumentation complications: Steroid use, smoking, cancer, prior radiation therapy, multiple trauma, and poor nutrition. These factors can affect a patient's ability to heal a biologic procedure (fusion), diminish bone quality, and/or increase the risk of infection.³⁸ Nutritional status can be assessed and improved if surgery is elective. Smoking cessation before spinal reconstructive procedures can improve fusion rates: smoking delays a spinal fusion and may contribute to an increased incidence of instrumentation complications.⁴²

Biomechanical Failure

Biomechanical failure sometimes results in pedicle screw or rod loosening/breakage.⁴³ With any instrumented fusion, it is a race between failure of the instrumentation and healing of the fusion procedure. Without the presence of a bony fusion, instrumentation is ultimately likely to fail. In addition, poor bone quality may lead to limited purchase, failure at the bone-screw interface, or pull-out/toggle and weakening of the construct. Lumbosacral junction (LSJ) is a well-known lesion that would be damaged according to the increase in the length of the instrumented segment, leading to the incidence of adjacent segment disorder.⁴⁴ Especially destruction of L5–S1 facet joint can lead to devastated LSJ instability, which spine surgeons should take care of.

A retrospective clinical study has shown that sacral screw inserted in tricortical purchase, which penetrates into the apex of the sacral promontory, is the most rigid purchase compared with bicortical (penetrates anterior and posterior cortex) or monocortical (posterior cortex only) purchases.⁴⁵ It is also reported that long fusion can affect on the iliosacral joint, which implies the necessity of iliac screw fixation in long fusion surgery.⁴⁶

Lumbar interbody devices placed via a posterior interbody route (PLIF) can sometimes lead to the cauda equina and nerve roots at risk during insertion because of the retraction required to insert the cage^{47,48} These cages should be large enough to engage the disc endplates but not too large to force overretraction of the neurologic elements. Transforaminal cage insertion (transforaminal lumbar interbody fusion, TLIF) places the exiting and traversing nerve roots on the side of insertion at risk than the PLIF approach. Both PLIF and TLIF procedures destabilize the posterior tension band supporting structures and require supplement posterior stabilization.

Subsidence of the cage can result in subsequent pseudarthrosis, as well as loss of foraminal height resulting in radicular symptoms. In such situation, cage loosening or back out can happen. Previous study has reported a relationship between vertebral endplate cyst formation in the early postoperative period and nonunion after lumbar interbody fusion, suggesting that the endplate cyst formation is a useful early predictor of subsequent nonunion.⁴⁹

Error in Procedures/Application

In anterolateral approach, orientation and proper patient positioning are the first steps in avoiding aberrant screw placement with potential neurologic or great vessel injury. The anatomy can be deceiving in the operative room in patients with rotational deformities, local trauma, infection, or tumor. Screws should be directed anteriorly to minimize risks to the neural structures under the maintained direct lateral posture. In other words, inadvertent problems can occur if the spine/pelvis assumes a more oblique orientation during the surgery.

In posterior approach, pedicle screw-based systems are the workhorse instrumentation systems, with its complication rate of 2.4%. The most common complication is pain (23%) related to pseudarthrosis or the implant itself. Nerve root irritation was uncommon (0.2%) despite 1% of screws penetrating either medial or inferior to the pedicle wall.⁵⁰ The lower incidence of medial wall fractures and lower risk of neurologic injuries should be due to the anatomical features of relative thickness of the medial pedicle wall, and pedicle-nerve distance (1–2 mm). In another studies, the rate of implant removal due to pain is relatively low and nerve root irritation is also uncommon (range: 0.2% to 5% in various series).

Complications from other posterior implants, such as hooks and sublaminar wires, have been reported. Sublaminar wires run the risk of neurologic injury and cutting out of bone by sawing through the lamina, which sometimes represent a source of neurologic injury. Hooks should not be placed in regions of canal narrowing secondary to degenerative, traumatic, or deformity-based stenosis.⁵¹ In both approaches, osteoporosis can lead to loss of fixation and screw cutout into the disc space, plowing through the vertebra, or lifting off/backing out of the vertebral body. Osteoporosis or damage to the endplate can lead to excessive subsidence and loss of fixation.⁵² There have been some reports regarding perioperative osteoporosis treatment. Ohtori et al. have reported that daily subcutaneous

injection of teriparatide for bone union using local bone grafting after instrumented lumbar posterolateral fusion in osteoporotic women was more effective than oral administration of bisphosphonate.⁵³

POSTOPERATIVE SPINAL INFECTION

Incidence

Spinal infection rates range from approximately 1% for microdiscectomies to 5–6% for instrumented decompression and fusions.^{54–60} During the surgery cases requiring more extensive soft tissue dissection, longer operative time, greater blood loss, more significant soft tissue devitalization, or the creation of dead space has an increased infection rate.

Other theories postulate that local soft tissue inflammation and postoperative seromas may serve as a potential cause for the increased infection risk seen with instrumented fusions. Complete neurologic injury significantly increases the risk of postoperative infection with the rate ranging from 9% to 15% in the spinal trauma patients.^{61,62}

Classification

Two major classifications of postoperative spinal infections are shown below:

Severity: (1) Superficial or deep infection with a single organism, (2) deep infection with multiple organisms, and (3) deep infection and myonecrosis with multiple or resistant organisms.

Host response: (1) normal systemic defenses, metabolic capabilities, and vascularity; (2) local or multiple systemic diseases including cigarette smoking; and (3) immunocompromised or severely malnourished.

Risk Factors

We have to consider some risk factors for postoperative infection before surgery, which are divided into modifiable and nonmodifiable risk factors (Table 126.2).⁶³

For the patients with modifiable factors, surgeon should work on the patients to address the factors. Smokers have a significantly increased chance of developing postoperative infections.⁶⁴ Thus, smoking cessation counseling should be a routine part of the preoperative meeting between surgeons and patients. Obese patients are also considered at high risk of developing postoperative infections.^{65,66} Overweight patients often require more extensive

dissection through poorly vascularized adipose tissue. The resulting tissue devitalization and fat necrosis result in an environment favoring bacterial growth and proliferation. In addition, the increased operative time and blood loss necessary with obese patients increase their risk of infection. Obesity in itself is a risk factor for malnutrition, diabetes, and other medical comorbidities, further contributing to a poor healing environment with diminished immunogenic potential.

Malnutrition is seen in approximately 25% of all elective lumbar fusion patients, which should be considered preoperatively as a potentially modifiable factor.

Diabetes mellitus gives high incidents of postoperative infection of 17%. Elevated blood glucose concentrations, particularly those above 200 mg/dL, can inhibit host immune response including cellular chemotaxis and phagocytosis. In addition to creating a relatively immunocompromised state, poorly controlled diabetics are predisposed to chronic medical conditions including hypertension, cardiovascular disease, and renal insufficiency. Careful preoperative attention to tight blood glucose control and evaluating other related factors may limit the risk of local infection and systemic morbidity in diabetics.

Nonmodifiable risk factors shown in Table 126.2 can be optimized by enough evaluation before surgery. Although age is not considered an independent risk factor, older patients are more likely to have comorbidities associated with an increased risk of postoperative infection.

Table 126.2: Risk factors for postoperative spinal infections.

Modifiable	Nonmodifiable
Smoking	Rheumatoid arthritis
Obesity	Acquired immunodeficiency syndrome (AIDS)
Surgery length	Adrenocortical insufficiency
Prolonged indwelling catheter use	Long-term corticosteroid use
Length of hospital stay	Malignancy
Malnutrition	Pre- or postoperative local radiation
Serum albumin < 3.5 g/dL	
Total lymphocyte < 1500/mm ³	
Recent weight loss > 10 pounds	
Transferrin < 150 mg/dL	
Abnormal skinfold measurements	
Diabetes mellitus	
Malnutrition	

Microbiology

The potential sources for postoperative infections are (1) direct inoculation during the operative procedure (the most common), (2) contamination during the early postoperative period, and (3) hematogenous seeding.^{54,67,68} Especially, fecal contaminants are more likely to be involved in surgeries of the low lumbar or sacral regions; bladder or fecal incontinence may predispose to Gram-negative flora, especially with posterior lumbosacral incisions. Gram-positive cocci are the most common pathogens responsible for acute postoperative infections. The most commonly reported organism is *Staphylococcus aureus*, which causes >50% of the infections.^{54,65,69} Other common Gram-positive species include *Staphylococcus epidermidis* and β -hemolytic streptococci. Common Gram-negative organisms cultured from infected surgical sites include *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumonia*, *Enterobacter cloacae*, *Bacteroides*, and *Proteus* species.⁶³

Infections that present >1 year after surgery are generally caused by low-virulence organisms such as coagulase-negative *Staphylococcus*, *Propionibacterium acnes*, and diphtheroids,^{70,71} those comprise normal skin flora. These low-virulent organisms are usually rapidly cleared by the host immune response with appropriate treatment and generally do not result in a clinical sepsis.

Hematogenous systemic spread can also cause surgical site infections. These infections are often associated with systemic illness and sometimes have grave consequences such as multisystem organ failure. Repeated cannulization of the venous system can lead to a higher incidence of Gram-negative infections.⁶⁵

Diagnosis

Clinical Presentation

Pain is the most common complaint. Patients will generally have an interval pain-free period immediately following the surgery for approximately 1–2 months and subsequently develop increasing pain over several weeks. This irregular postoperative course from pain free to painful gives us the suspicion of postoperative infection. Superficial wound infections generally present within 2 weeks of surgery with local pain, erythema, drainage, and warmth. This would be treated with local wound care and oral antibiotics for approximately 2 weeks. However, if a wound continues to drain after extensive local care or if the patient develops increasing operative site pain with the development of

constitutional symptoms, it must implies an underlying deep infection. Examination of the surgical site may reveal increased erythema, edema, tenderness to palpation, and drainage.

Late infection presenting >2 months after the surgery can be difficult to diagnose because of the lack of obvious symptoms. Increasing pain at the surgical site or the presence of constitutional symptoms should prompt suspicion of an underlying infection in either the early or late postoperative time periods.

Laboratory Testing

White blood count (WBC): An elevated WBC implies infection, but is not an absolute indicator. Neutrophils tend to increase in acute infection with fever, while lymphocytes in viral infections. In the early postoperative period, surgical stress can initiate intravascular leukocyte demargination that causes an increased WBC. In addition, lack of significant elevation in WBC does not necessarily rule out an infection, especially in patients with immunosuppression. Chronic slight elevation in WBC count may imply smoking.

Erythrocyte sedimentation rate (ESR): ESR elevates following the surgery and may not normalize until 3–6 weeks postoperatively.^{72,73} Peak ESR levels have been shown to correlate with the degree of invasiveness of the surgery, with more extensive surgeries causing higher ESR elevations than less invasive procedures.⁷⁴

C-reactive protein (CRP): CRP values rise sharply during the initial postoperative period and decreases baseline levels more rapidly. CRP levels generally peak on the third day postoperatively and return to baseline within 10–14 days. This rapid normalization makes CRP a more sensitive indicator of infection and a more useful diagnostic tool when determining the presence of infection, especially in the acute and subacute postoperative period.^{72–77} Abnormal elevation of these factors outside of the postoperative period can indicate the evidence of developing infection.

Blood cultures: Cultures can provide the information about the culprit organism; however, one obtained from the superficial wound is often contaminated with skin flora and can confuse the diagnostic workup. In case with suspicious contamination, early aspiration of a suspicious wound can be of use.⁷⁸ Also, cultures should be taken in a septic individual with temperature of over 38.5°C before the initiation of antibiotics. If the blood cultures are positive and provide identification of an organism, it can be presumed that the same organism is the cause of the spinal infection.

Imaging

Plain radiograph: Findings on plain radiographs are the first and basic clues for infection such as adjacent bony lysis adjacent to the instruments as well as their loosening, or disc space narrowing. However, these findings generally appear 4–6 weeks postoperatively, and often should require to be passed before the findings of infection up to 4 weeks.⁷⁵ More significant radiographic findings such as reactive bone formation, endplate destruction, osteolysis, and deformity indicate a more significant infectious process and usually require at least 2 months to develop.

CT: CT provides a more detailed view of spinal anatomy and evidence for the infection than plain radiograph does such as endplate changes, bony lysis, and/or soft tissue fluid collections. Computed tomography-guided biopsies can also be used to provide an aspirate for culture or tissue biopsy from infected soft tissue or bone as noted earlier.

Magnetic resonance imaging (MRI): MRI is the most important imaging modality with high accuracy (93% sensitivity and 96% specificity).^{79–81} Magnetic resonance imaging can identify postoperative osteomyelitis, discitis, and epidural abscesses. An epidural abscess will display a T1 isointense fluid collection with potential obliteration of the otherwise well-defined neural elements, and the T2-weighted images (WI) show significant increased intensity. Abscesses will display ring enhancement on T1 images following the addition of IV gadolinium. Osteomyelitis appears as areas of vertebral body and disc space hypointensity on T1WI and hyperintensity on T2WI. Discitis typically include hypointensity on T1WI and hyperintensity on T2WI in adjacent vertebral marrow (Figs. 126.9A and B). All cases of discitis displayed intervertebral disc signal enhancement with the addition of a contrast agent.⁸²

Nuclear medicine studies: Though its use is supplemental, it is helpful being free from the implant-associated artifacts unlike other modalities. Bone scans are often non-specific and may show generalized uptake around the surgical site in a postoperative spinal infection.⁷⁵ Technetium-labeled ciprofloxacin, when combined with single photon emission computed tomography, has been shown to have improved accuracy, particularly if performed >6 months after the surgery.⁸³ Recently, 18F-fluorodeoxyglucose-positron emission tomography has been reported to be of use for diagnosing pyogenic spondylitis in patients (Figs. 126.10A to D).⁸⁴

Figs. 126.9A and B: A 57-year-old man who underwent L3–L4 posterolateral fusion for lumbar spinal stenosis complained of lower back pain 4 months after the surgery and diagnosed as postsurgical discitis by the following radiographical examinations. (A) Plain radiograph shows the decreased interbody space with consolidation along the endplates and vacuum phenomenon. (B) Magnetic resonance imaging (MRI) shows low-intensity lesion in the disc and adjacent marrow (T1-weighted image) and high-intensity lesion in the corresponding area (T2-weighted image).

Figs. 126.10A to D: A 50-year-old man underwent posterolateral fusion surgery (A). Magnetic resonance imaging (MRI) indicated high-intensity lesion at the L4–L5 intervertebral disc level (B): T2-weighted image. Fluorodeoxyglucose-positron emission tomography showed abnormal accumulation in the L4–L5 level (C). The patient showed abnormal blood data (white blood cell 6200 cells/mm³ and C-reactive protein 2.70 mg/dL). Signs of infection on MRI were observed at the L4–L5 level 4 weeks later (D: T2-weighted image).⁸⁴

Prevention

The use of preparative prophylactic antibiotics is routine for most surgeons. Perioperative infection rate is 2.2–4.3% with preoperative antibiotics administration and 5.9–12.7% without.^{85,86}

In order for antibiotics to be effective prophylactic agents, they must have adequate spectrum and penetration ability into tissues adjacent to the surgical site in sufficient concentrations. Before the surgery, antibiotic administration should begin 30 minutes to 1 hour preoperatively followed by repeating after 4 hours of surgery.^{87,88}

Cephalosporin is an excellent candidate for prophylactic antibiotics for its good coverage against the common bacterial agents in spinal infection: First-generation cephalosporins are good antibiotics for prophylactic administration with strong gram-positive coverage (*S. aureus* and *S. epidermidis*) as well as against common gram-negative organisms (*E. coli* and *Proteus*). Cefazolin continues to be the most commonly administered prophylactic antibiotic for its appropriate antimicrobial coverage, relative inexpensiveness, and rapid elevation in systemic concentration.

Drug penetration should be considered and be maximally effective as the spine is composed of several different tissues from bone to soft tissue. Cefazolin displays a longer half-life in the serum and bone.^{86,89,90} Regarding the penetration of antibiotics into intervertebral discs, it varies according to the disc aging; Penetration of antibiotics into the adult intervertebral disc depends on passive diffusion from adjacent bony structures and cartilaginous endplates, as well as from the annulus fibrosus.⁹¹ Thus increased age and decreased disc vascularity inhibit the antibiotic penetration into the disc. Molecular charge of an antibiotic is an important determinant of its ability to diffuse into the disc. Positively charged antibiotics such as gentamicin and vancomycin have been shown to freely penetrate the annulus fibrosis and nucleus pulposus, whereas negatively charged antibiotics such as penicillin are found in the annulus fibrosis but not the nucleus pulposus. Recently, linezolid is a novel antibiotic that has been approved for treatment of methicillin-resistant *S. aureus* (MRSA) infections, and clinically attractive alternative to vancomycin due to its mild side effect profile and oral bioavailability, while it is reported to be inferior to vancomycin in experimental MRSA discitis rabbit models.⁹² Thus Linezolid can be inadequate for the treatment of spine infection limited to the intervertebral disc, but may be effective for

the treatment of infection extending into the muscle and bone marrow, such as in vertebral osteomyelitis, iliopsoas abscess, and postsurgical infection.⁹³ Antibiotics strategy should include antibiotic-resistant organisms, such as MRSA or vancomycin-resistant enterococci (VRE), which are associated with significantly increased morbidity, mortality, and cost. Some of the risk factors associated with MRSA include prolonged use of antibiotics, previous exposure or infection with MRSA, indwelling catheter use, advanced age, and intensive care unit stay.

Intravenous antibiotics are usually administered for approximately 6 weeks followed by approximately 6 weeks, or longer, oral antibiotics. The specific time for treatment depends on the virulence of the infectious organism and its sensitivity to the antibiotics. Regular follow-up of infectious laboratory markers including WBC, ESR, and CRP assists in determining the response to treatment.

Hematomas can occur and precede the infection at the surgical site by providing a significant milieu for bacteria proliferation. Postoperative closed suction drainage is useful to prevent hematomas. Limiting blood loss with meticulous attention to hemostasis, débridement of necrotic tissue, and periodic release of retractors helps to minimize possible sites of infection.⁹⁴ In patients with significant infections or soft tissue involvement, the use of reconstructive soft tissue techniques including flap coverage may be necessary.

Management

In managing postoperative spinal infection, prompt diagnosis with isolation of a specific organism and initiation of appropriate medical and surgical management are important. Primarily a minimum of two sets of blood cultures should be taken and WBC, ESR, and CRP measurements should be used to detect the infection and monitor the treatment. If those do not help to determine the organism, biopsy can be optional. After the identification of organism, appropriate antibiotic therapy should be initiated. Extremely superficial infections such as a stich abscess can be treated with 2 weeks of oral antibiotics. For any significant infection, however, a minimum of 6 weeks of intravenous antibiotics followed by 6 weeks of oral antibiotics should be used. In addition to the antibiotics, most significant superficial and deep infections will require surgical débridement. When involved in the infection, the deep fascial layers should be opened and all loose tissue and foreign material should be removed. Infectious specimens

should be investigated for bacterial studies including aerobic, anaerobic, fungal and acid-fast studies.

The ultimate goal of any intervention is eradication of the infection, adequate wound closure and maintenance of vertebral column stability. The approach to treatment often requires aggressive and sometimes repeated débridement to prevent recurrence of infection until the tissues appear clean and operative cultures are negative. Vacuum-assisted closure for deep infection after spinal instrumentation is useful in dealing with patients susceptible to wound infections, especially those with neuromuscular diseases such as Duchenne's muscular dystrophy and cerebral palsy.⁹⁵

In case of epidural abscess, early recognition and prompt intervention, particularly surgical débridement should be considered. With progression of the disease, the patient may show signs of increased back pain, systemic symptoms and eventually neurologic deficit. Diabetes patients sometimes show no fever and pain, which can be diagnosed using laboratory tests with ESR and CRP.

Spinal Instrumentation and Infections

The use of instrumentation in spinal procedures results in a higher risk of developing a postoperative infection with approximate incidence rate of 5–6%.^{54,70} Implants provide avascular surfaces on which bacteria can create a glycocalyx, which serves as a barrier to the host immune response and antibiotic treatment. Although recent titanium systems theoretically will decrease the affinity of bacteria to the surface of the device,⁹⁶ unintended wear debris may be greater with titanium implants in a developing pseudarthrosis with implant interface micromotion leading to a more robust inflammatory response.^{97,98}

The implants should be inspected during evaluating suspected infections, and if the implants show obvious signs of loosening, they should be removed and replaced if necessary. It is still to be discussed whether to remove the implant or not in postoperative infection. Some authors advocate complete removal of all instrumentation, independent of fixation and fusion status, because of the difficulty of eliminating the infection without removal.^{99–101} Leaving instrumentation at the time of débridement has been sometimes recommended to prevent possibly catastrophic spinal instability. If the infections persist, the instrumentation can be removed after the arthrodesis has been achieved; however, vertebral column malalignment, spinal cord compression, and paralysis are potential

complications associated with instability if fusion is not complete at the time of instrumentation removal.

KEY POINTS

- **Neurologic injuries:** Neurologic injuries can happen directly or indirectly, and if there is the potential for recovery, this may occur over 12–18 months. Be careful not to retract the nerves too hard especially at the L1–L2 level, i.e. the level of the conus medullaris. Deformity correction surgery involves potentially higher risk of neurologic injuries. Neuromonitoring is also helpful during the surgery.
- **Dural injuries:** Incidental durotomy occurs with average 3.5% incidence in primary discectomy and 13.2% in revision discectomy procedures. The most common instrument leading to durotomy is the Kerrison punch followed by the curette and then the drill. Every surgeon regardless of experience may encounter a durotomy. Careful preoperative planning and meticulous surgical technique can prevent durotomy in some but not all cases, and early diagnosis and repair is important during the surgery.
- **Vascular complications:** Direct or indirect injury causes vascular complications. Anterior approach tends to lead to more vascular complications because of the existence of great vessels in the retroperitoneal space. Insufficient hemostasis in anterior approaches can lead to fatal bleeding and hematoma as the approach lacks the chances of compressed hemostasis as is in posterior approach. In posterior approaches, the segmental vessels arising off the aorta form radicular branches that then pass through the neuroforamina to form the anterior and posterior spinal arteries.
- **Instrumentation complications:** Spinal instrumentation complications can mainly occur from biological, biomechanical, and procedural failures. Loosening, breakage, or infections in implants lead to biologic failures. In arthrodesis procedures, without the presence of a bony fusion, instrumentation is ultimately likely to fail. Surgeons have to carefully plan their instrumentation surgery preoperatively.
- **Postoperative spinal infection:** Spinal infection rates range from approximately 1% for microdiscectomies to 5–6% for instrumented decompression and fusions, involving superficial to deep tissue infections. The most commonly reported organism is

S. aureus followed by gram-positive species include *S. epidermidis* and β -hemolytic streptococci. Infections that present >1 year after surgery are generally caused by low-virulence organisms or through hematogenous seeding. Patients will generally have an interval pain-free period immediately following the surgery for approximately 1–2 months with increasing pain. Laboratory test using WBC, ESR, and CRP and blood cultures are needed. Routine preoperative prophylactic antibiotics using Cephalosporins or Cefazolin are recommended to prevent postsurgical infection.

- » Neurologic Intraoperative Monitoring
- » Management of Intraoperative Neurologic Loss

INTRODUCTION

The current spinal instrumentation available has allowed more aggressive surgeries for better deformity correction, reconstruction, stabilization, and decompression. This is particularly so for the rigid screw and rod systems that allow translation and derotation in deformity correction, and maintains this correction as fusion along the spine takes place. However, together with their intrinsic benefits, these procedures do come with risks and complications. Having knowledge and understanding of potential complications, the surgeon is able to adequately educate the patient as to the surgical risks and benefits of the procedure, and improve patient safety.¹ Risk awareness provides the surgeon with a better chance of avoiding complications and managing any that occur.² More common complications of spine surgery include infection, implant failure, and nonunion; neurologic complications are the most devastating. Strong corrective forces applied to the spinal deformities have serious risks for neurologic deficit including loss of motor function in the lower extremities.³ Though the risk seems low, the overall effect is tremendous to the patient; therefore, it is imperative to discuss the risk of neurologic injury to the patient and the family before surgery (Table 127.1).⁴

Minimizing neurologic injury begins with careful preoperative evaluation, identifying risk factors present in the patient and adequate preparation before surgery. The surgical plan must be well designed using sufficient

preoperative imaging modalities, and having the appropriate equipment available for surgery including proper working instruments, intraoperative neurologic monitoring, and image intensifier. Accurate documentation of the surgical steps undertaken can help to identify the cause of signal change, avoiding delay in doing appropriate remedial action.¹³ Sufficient postoperative care should also be anticipated; therefore, the need for having the patient admitted at the intensive care unit should be foreseen. Identifying the complications comes with a thorough understanding of its etiology, enabling the surgeon to institute immediate management to minimize its ramifications.

IDENTIFICATION OF HIGH-RISK FACTORS

Before surgery, identify high-risk patients and adequately prepare them for surgery. Suffice to say that a careful history and accurate physical examination should be performed and findings should be well documented. Abnormalities or asymmetry in the neurologic examination or excessive back pain are a cause of concern. Absence or asymmetry of abdominal reflexes suggests an intraspinal lesion such as syringomyelia. Proper imaging and diagnostics should be performed before surgery. Computed tomography (CT) scans help to identify and describe bony abnormalities, such as hemivertebrae. Male gender, patients younger than 11 years old, and abnormal

Table 127.1: Risks of neurologic complications for different spine procedures.

<i>Procedure</i>	<i>Risk</i>	<i>Author</i>	<i>Comments</i>
Spinal deformity surgery	0.01–0.05%, 17%	Bridwell et al.; ⁵ Wilber et al. ⁶	
Scoliosis surgery	0.3–1.4%	Winter; ⁷ Coe et al. ⁸	
Combined AP scoliosis surgery	1.87%	Diab et al. ⁹	Increase from 1% in anterior alone
Spine surgery in pediatric population	2.2%	Thuett et al. ¹⁰	0.17% for actual rate of permanent deficit
PLIF and TLIF	4.9%	Chrastil and Patel ¹	Range 0–7% 7.3% (from 2% to 14%) risk of dural tear 5.3% (from 0% to 11%) risk of post-operative radiculopathy/radiculitis
Anterior cervical spine surgery	0.2–0.9%	Daniels ¹¹	Iatrogenic spinal cord injury
Scheuermann's kyphosis	1.9%	Coe et al. ¹²	

(PLIF: Posterior lumbar interbody fusion; TLIF: Transforaminal lumbar interbody fusion; AP: Anterior-posterior).

superficial abdominal reflexes were significantly associated with neural axis abnormalities; therefore, routine use of magnetic resonance imaging (MRI) in this subset of patients is recommended.¹⁴ Other considerations for pre-operative MRI scanning include left thoracic curve pattern in idiopathic scoliosis, particularly in male patients or patients with severe curve.¹⁵ A 21.7% prevalence rate for neural axis abnormalities in infantile idiopathic scoliosis has been reported,¹⁶ and proposed total spine MRI evaluation at the time of presentation in those with curves measuring $\geq 20^\circ$. However, more recently, in the largest evaluation of intraspinal anomalies in infantile idiopathic scoliosis, a lower percentage (13%) of neural axis abnormalities in MRI was reported, with the recommendation of close observation as opposed to immediate screening MRI in patients with presumed infantile idiopathic scoliosis (IIS) and a curve $>20^\circ$. Table 127.2 lists down patients with higher risks of intraspinal abnormalities, suggesting evaluation using an MRI should be done.^{17–19}

Patients with comorbidities and concurrent medications should also be recognized. Medications, such as anti-inflammatory medications and aspirin, should be withheld to minimize intraoperative and postoperative bleeding. Patients with cardiopulmonary comorbidities have been reported to carry a higher risk for having electrophysiological events during spine surgery.²⁰ The decreased cardiopulmonary reserve compromises their ability to oxygenate the blood increasing the risk for ischemic injury to the cord.

Age is an important factor as well, having an increased risk for neurologic injury in adults with long-standing

Table 127.2: Patients with higher intraspinal abnormalities (MRI suggested).

Infantile or juvenile idiopathic scoliosis
Congenital anomalies
Atypical curves in adolescent idiopathic scoliosis (including apex left thoracic curve, double thoracic curves)
Apical thoracic kyphosis
Rapidly progressive curvature
Excessive headaches, atypical back pain
Abnormal neurologic examination

deformities. A review of 683 spinal fusion procedures for Scheuermann's kyphosis (mean patient age at 21 years, range: 5–75 years), with the majority (73%) of patients ≤ 19 years old, reported that complications were more common among adults (22%) with the no difference on the overall incidence of complications between the posterior spinal instrumentation (PSF) (14.8%) and same-day ASF/PSF (16.9%) procedures.¹²

Incidence of ossification of posterior longitudinal ligament (OPLL) is found to be 70% in the cervical spine,

15% in the upper thoracic spine, and 15% in the proximal lumbar spine.²¹ In the thoracic spine, it is usually seen in the upper- and midthoracic spines of women who are older than 40 years.²² Due to the inherent anatomic and physiologic factors of the thoracic OPLL, surgical success appears to be less compared to cervical OPLL. Anatomic considerations of the thoracic spine include (1) kyphosis, limiting backward movement of the cord during posterior decompression; (2) relative avascularity of the thoracic cord compared to the cervical, making it more sensitive to ischemia during manipulation, and (3) the presence of the rib cage, limiting the exposure.²³ Since the ossified ligament is strongly adherent to the dura, direct removal is difficult and can compromise the cord during decompression. When OPLL occurs in conjunction with ossified yellow ligament (OYL), severe thoracic myelopathy can occur. Performing laminectomy can cause alteration in spinal alignment and may cause neurologic compromise during surgery.²⁴ This is due to the presence of the OPLL anteriorly that can cause impingement when alignment changes. Li advocates stabilizing the spine in situ rather than correct the kyphosis when performing instrument fixation in thoracic OPLL.²³

Kyphoscoliosis poses an increased risk for cord ischemia due to long-standing vasoconstriction of the spinal arteries²⁵ as well as the decreased radicular-medullary arteries in the thoracic region.²⁶ Therefore, acute distraction may reduce the vessel caliber, subsequently decreasing spinal cord blood volume (oxygenated hemoglobin plus deoxygenated hemoglobin). This was demonstrated by Macnab²⁷ using near infrared spectroscopy, wherein changes were evident within 1 second of the intervention beginning and return to the baseline at the end of each intervention.

Revision surgery poses an increased risk for morbidity because of its complexity and technical demand compared to primary surgeries. Raynor et al.²⁸ report a statistically significant higher incidence of true positive events in revision surgery (6.09%) versus primary surgeries (2.27%). Furthermore, he reports that intraoperative monitoring reduced the potential incidence of neurologic deficit. He concludes that revision spinal surgery and lack of improvement in IOM data despite intervention have a significantly higher risk of postoperative neurologic deficit.

Other procedures associated with high risk include vertebral osteotomies and kyphosis correction.^{9,29,30} With the innate stiffness of the thoracic column, the deformities are less flexible, and neural structures more sensitive in deformity correction. In posterior shortening procedures,

neurologic risk continues to be a feature in these surgeries.³⁰ Neurologic deficit can take place during abrupt subluxation, laminar impingement, or cord buckling. vertebral column resection (VCR) acutely destabilizes all three spinal columns; therefore, it is obligatory to use a temporary rod for stabilization before osteotomy, preventing deficit initiated by sudden translation. Restoring the anterior height by using cages or bone grafts can address excessive buckling (Table 127.3).³⁰

Identification of patients with difficulty in performing neurological intraoperative monitoring is imperative to have proper preparations. Patients with neuromuscular scoliosis were significantly less likely than adolescent idiopathic scoliosis to have successful motor-evoked potentials (MEPs) and less likely to have a successful somatosensory-evoked potential (SSEP). Successful MEP is less likely to be successful in patients with kyphosis than in idiopathic scoliosis. Both MEP and SSEP were significantly less likely

to be successful in patients with cerebral palsy. A study by Vitale showed 83% success rate with SSEP and 72% success rate with MEP monitoring in patients with neuromuscular deformity, lower than those for patients with idiopathic scoliosis.²⁰

MECHANISMS OF NEUROLOGIC INJURY

Neurologic injury can either be due to direct trauma or indirectly through an ischemic insult to the spinal cord. Some studies have demonstrated that postoperative sensory deficits are more likely to be caused by direct trauma to the dorsal columns, whereas paraplegia is more likely to result from an ischemic insult to the anterior and central portions of the cord.³² Direct trauma can be caused by structural injuries during exposure, decompression, and instrument placement, by laceration, compression, traction or avulsion injuries to neural elements. Indirect trauma is a result of disruption of the blood supply to the neural structures, resulting to ischemia and disruption of axoplasmic flow, as seen in excessive blood loss leading to hypotension. Physiologic variables, such as systemic blood pressure, intravascular volume, and blood hemoglobin concentration, affect blood flow and oxygen delivery to the spinal cord. Combined with structural changes to spinal cord vasculature, indirect injury to the neural elements is introduced and neurologic deficits might be produced. Hypotension may induce spinal cord ischemia even without spinal cord manipulation.³¹ Other maneuvers cause indirect trauma including excessive thecal sac retraction in stenotic patients, distraction of the spinal cord in a rigid spinal deformity, and cord compression after corrective maneuvers, leading to decreased vascular perfusion damaging neural structures.^{33–35} Compression of the thecal sac to <45% of its cross-sectional area can bring changes in motor and sensory conduction.³⁶ Postoperative hematoma formation can compress the neural structures leading to neurologic deficits; thus, meticulous hemostasis should be observed. Traction or direct compression also induces indirect injury to the neural structures as in improper positioning and lack of padding to cushion the patient during surgery leading to peripheral nerve injury after spinal surgery. The ulnar, posterior interosseous nerve, the peroneal and lateral femoral cutaneous nerves are prone to injury through external pressure.

Neurologic deficits can present with a spectrum of symptoms, from radicular pain, paresthesia, numbness and weakness, to complete loss of function. It can be stratified

according to severity, whether it is minor or major, complete or incomplete, or transient or permanent impairment. Minor deficits include radicular pain, which is the most commonly reported by postoperative symptom of neurologic injury.¹ Major deficit would encompass several roots with both motor and sensory deficits.

NEUROLOGIC INTRAOPERATIVE MONITORING

With the emergence of intraoperative monitoring, surgical neurologic deficit can be prevented.³⁷ It is most beneficial during critical stages of spine surgery when the risk of neurologic injury increases.³⁸ A reliable neurologic monitoring technique should be able to detect spinal cord injury when it has been incurred, allowing the surgeon prompt recognition of the injury and appropriate corrective measures can be taken immediately, preventing irreversible neural structure damage and optimizing the chance for recovery. The ideal monitoring technique should be able to provide prompt warning but with minimal surgical interruptions; it should be reproducible and measurable. Stimulation can be applied to peripheral nerve sites to the motor cortex site on the scalp or directly to the spinal cord and recordings are taken accordingly. Evoked potential signals recorded at the dura are more stable than those from the scalp.³⁷

Spinal cord monitoring should be considered as an integral part of surgery for spinal deformity, allowing early detection of complications and possibly prevent neurologic morbidity in patients undergoing spine surgery,^{3,28,39,40} particularly for corrections of scoliosis >45° and in congenital spinal anomalies.⁴¹ It has been demonstrated that intraoperative spinal cord monitoring facilitates detection of impending spinal cord deficit and early responses that are likely to preserve spinal cord function.⁴⁰ The wake-up test can be a functional supplement in the detection of neurologic spinal cord deficits.³

False-negative cases refer to those in which the evoked potentials (EP) remain stable throughout the surgical procedure but the patient was found to have a postoperative neurologic deficit. False-positive results are those in which the EP changes that could not be related to any event that might imperil the cord function but the patient did not present with any postoperative neurologic deficit. A true negative outcome did not show any significant intraoperative change in EP and patient did not have any postoperative neurologic sequelae. A true positive result is defined as a change in the waveform that could be correlated with

Table 127.4: Interpretation of results.

	<i>True positive</i>	<i>True negative</i>	<i>False positive</i>	<i>False negative</i>
EP change	+	–	+	–
Neurologic deficit	+	–	–	+

a surgical event with or without a postoperative neurologic deficit. A false-positive warning rate of 2.2% was reported by Luk et al.³⁸ SRS survey as reported by Nuwer⁴² showed the overall false-negative rate to be 0.127% and the overall false-positive rate to be 1.51% (Table 127.4).

Abnormalities in recordings can be detected during curve correction, hypotension (MAP < 50 mm Hg), direct cord trauma, and malposition in pedicle screw.^{20,41} Other causes for loss or significant degradation of monitoring data, as identified by Thuet,¹⁰ include instrumentation, wound or nerve root retraction, halo/femoral traction, malposition or compression of peripheral limb, hemostatic matrix in spinal canal, and partially occluded endotracheal tube. Lotto⁴¹ also attributes signal changes to hypothermia and hyperthermia.

Somatosensory-Evoked Potential

Developed in the 1970s, SSEP monitoring serves as an early warning technique in detecting deficit during surgery.^{43,44} Somatosensory-evoked potential monitoring assesses the functional status of peripheral nerves and the dorsal sensory pathways (tactile discrimination, vibration, proprioception). The sensory-evoked potential (SEP) is the electrical response of the brain to an applied somatosensory stimulus; response is elicited by stimulating either a sensory or mixed peripheral nerve (median nerve, ulnar nerve, posterior tibial nerve, peroneal nerve) caudal to the operative site and can be recorded cranial to the operative site, like the scalp. The ulnar nerve is the preferred stimulation site for upper extremity SSEPs because the lower spinal nerve entry between C7 and T1 permits assessment of the entire cervical neural axis (Fig. 127.1).⁴⁴

Parameters continuously monitored throughout surgery include waveform amplitude (power of the signal) and latency (velocity of the signal) and compared with baseline, detecting injury.^{44,45} Amplitude and latency are recorded before skin incision and used as a reference baseline for subsequent monitoring. Change in amplitude is more sensitive to cord injury as it is unlikely to have injury without amplitude changes, while changes in latency

Fig. 127.1: Normal amplitude and latency. Amplitude is the power of the signal, while latency is the velocity of the signal.

are less relevant.⁴⁴ Data should be constantly updated to control for anesthetic and metabolic changes. Amplitude is sensitive to nitrous oxide, halogenated agents, hypothermia, hypotension, and electrical interference, while latency is affected by temperature. Chemically paralyzing the patient, such as in total intravenous anesthesia, diminishes myogenic interference enhancing the quality of response.⁴⁴ Baselines may be altered during different stages of surgery and should be noted before surgical procedures that may alter neurologic function such as deformity correction. Injury to the neurologic structures causes signal change such as decrease in amplitude and increase in latency. A 50% reduction in the amplitude or a 10% increase in latency is considered abnormal, requiring the surgeon's prompt attention.^{38,40,46} Alarm criteria vary from center to center but generally include an intraoperative unilateral or bilateral amplitude loss of at least 50–60%.⁴⁴ In our institution, another criteria which is >10 minutes of SSEP change is also used as an alarm criteria, as well as drop in amplitude differentiated into “quick change” that shows a decrease in amplitude to 30% within

30 minutes and “slow change” where amplitude drops to 60% for over 30 minutes (Fig. 127.2).¹³

It has been reported that marked changes in SSEP responses indicated a high chance of developing neurological deficit, and if there was no change, the chance of any neurological postoperative deficit was extremely low.^{28,47} Although it has safely reduced the risk of permanent neurological deficit, there are reports of false-negative cases where the patient awoke with a neural deficit not detected by SSEP.⁴⁰ There have been reports of paralysis, though rare, despite normal results of somatosensory monitoring.²⁰ Somatosensory-evoked potential monitoring is limited in that it can best detect injury limited to the ascending tracts but can give only indirect information about motor tracts. Therefore, damage to the motor tracts can occur without any resultant change in SSEPs. Somatosensory-evoked potentials have been reported to be 99% sensitive but only 27% specific in identifying neurologic deterioration.⁴⁸ There is a small but definite risk of false-negative findings when monitoring patients with pre-existing spinal cord compromise, such as myelopathy or acute spinal cord injury because of the sensitivity of the vascular supply to both the anterior and lateral aspects of the spinal cord, which is supplied by the anterior spinal artery. Hypotension-induced ischemic injury may not be detectable by SSEP monitoring at all or during the critical time needed to initiate intervention to prevent or minimize neural injury.⁴⁹ Recording SSEPs in patients with severe myelopathy, spinal cord tumor, obesity, or peripheral neuropathy either alone or in combination have also been shown to be difficult (Fig. 127.3).⁴⁴

Motor-Evoked Potentials

However, motor pathways are analyzed by MEP, thus has the advantage of detecting trauma to the descending motor tracts.²⁰ Response is elicited from motor pathways, including the corticospinal tract (CST), spinal cord interneurons, anterior horn cells, peripheral nerves, and skeletal muscles innervated by alpha motor neurons, after application of high-voltage transcranial electrical stimulus. A low-output impedance electrical stimulator generates a high-volume, short-duration stimulus or pulse train by a series of electrodes placed over different areas of the scalp to excite a specific motor cortical region, resulting to stimulation of CST axons coursing from the cortex through the internal capsule to the caudal medulla where the fibers cross over in the lower lateral brainstem and descend

Fig. 127.2: Significant SSEP tracing change. Tracing 1 shows baseline SSEP. Tracing 2 shows the change after curve manipulation, showing a decrease in amplitude.

into the lateral and anterior funiculi of the spinal cord. Corticospinal tract axons that come from the premotor and motor cortex enter the spinal cord gray matter, interact with spinal interneurons, and subsequently synapse with alpha motor neurons that supply peripheral muscle. Motor-evoked potentials can be recorded either from the spinal cord (I and D waves) or directly from muscle producing a compound muscle action potential (CMAP).⁴⁴ Transcranial motor evoked potentials (TcMEPs) from the CST can be recorded from the spinal epidural or subdural space by a catheter-type electrode or from peripheral musculature (Fig. 127.4).

The “D-wave” is the response recorded from the epidural space and represents direct activation of the

Fig. 127.3: The following tracings show baseline SEP tracings, followed by an abnormal tracing, with a decrease in amplitude, and eventual recovery (increase in amplitude) after correction.

CST cells. In awake or lightly anesthetized patients, the “D-wave” is followed by a series of “I-waves” that is generated indirectly by cortical synapses. These descending stimuli excite anterior horn cells and spinal alpha motor neurons, inducing a CMAP. However, setup is technically demanding because electrode placement is required, done percutaneously or through a laminotomy procedure. In addition, D-waves reflect global CST function that poses a difficulty in monitoring the cervical spinal cord because it might miss a selective injury to the cervical cord motor fibers that spares the lower extremity fibers. Therefore, it is both easier and preferable to record myogenic motor responses (CMAP) from upper (control) and lower extremity peripheral muscle.⁴⁴ CMAPs may be recorded from surface electrodes or subdermal needle electrodes placed over key peripheral muscles (Fig. 127.5).

Different alarm criteria for muscle MEP have been used, including all-or-nothing, amplitude, stimulation threshold, and morphology. The warning criterion is typically a 75% or more decrease in CMAP amplitude though individual differences should be considered.⁴⁴ In our institution, alarm criteria for MEP include the loss of 65%

Fig. 127.4: Motor-evoked potentials. Tracing 1 shows baseline, while tracing 2 shows a decrease in amplitude after manipulation.

Fig. 127.5: Spinal cord evoked potential (D-wave).

amplitude and increase in 10% latency.¹³ Complete loss of muscle MEP with at least 50% preservation of D-wave can result to transient paraplegia, whereas complete loss of D-wave amplitude during surgery is likely to have permanent motor deficit (Fig. 127.6).

Limitations of MEP include the following. Setup is technically demanding and is not a continuous measurement. Signal can be absent in up to 40% of myelopathy patients. It is contraindicated in deep brain stimulators or cochlear implants. It also cannot be applied for surgery caudal to T10 since it cannot recruit enough axons to generate D-wave with sufficient amplitude for monitoring. Neuromuscular relaxation causes changes in TcMEPs; thus, muscle relaxants should be avoided during critical parts of surgery, however can be used during low-risk portions of the procedure such as during spinal exposure. Motor-evoked potentials are greatly affected by inhalational anesthetics and total intravenous anesthesia for reliable recording is more optimal.^{3,44} Chemical paralysis will prevent elicitation of MEPs.⁴⁴ Other factors that affect

Fig. 127.6: Significant MEP (motor-evoked potential) changes. The first tracing shows baseline (normal) MEP signals. The second tracing shows a decrease in MEP signal, when the screw was inserted. The third tracing was taken during screw removal, showing an increase in the amplitude. The last tracing shows the recovery of MEP signals.

MEP include severe myelopathy, temperature, hypotension, and patient's height. D-wave [spinal evoked potential (SpEP)] is less sensitive to anesthetic agents. Both sensitivity and specificity in detecting injury are high as 100% and 95%, respectively.

Despite its technical setup complexity, TcMEPs are safe and effective in evaluating spinal cord motor tract function. Schwartz⁴⁰ reported on the safety of the procedure even in patients with cardiac disease, pace makers, and history of epilepsy. However, the most notable pitfall was the risk for tongue bite during cortical stimulation that causes severe jaw musculature contraction in patients without neuromuscular blockage.

An alternative to motor cortex stimulation is neurogenic motor-evoked potential (NMEP) that directly stimulates the spinal cord; however, it remains as an adjunct to

SSEP in monitoring sensory pathways.³ This is elicited by transosseous (spinous process, lamina) or epidural electrospinal stimulation and recorded over lower extremity peripheral nerves (e.g. popliteal fossae). Although initially, it was thought to be mediated within spinal motor tracts, researches have confirmed that both the neurogenic-evoked response and SSEPs are mediated through common spinal cord pathways; thus, it has remained as an adjunct to SSEP monitoring.³ Its advantages include technical simplicity in stimulation and recording, and are minimally affected by most anesthetic agents, including neuromuscular blockade. A neurogenic response is not a motor-evoked potential, but rather, represents antidromic spinal cord somatosensory activity. This has been confirmed in clinical practice by successful recording of NSEPs in paraplegic patients showing that this response does not depend on functionally intact motor tracts.⁴⁴ During occasions where SSEP, TcMEP, or H-reflex is difficult to elicit, epidural stimulation at the rostral thoracic level elicits a descending sensory potential that is recordable over the popliteal fossae.⁴⁴

The NMEP signal loss has been reported to occur before any corrective maneuvers and as late as 70 minutes after correction of kyphosis.⁵⁰ Causes of NMEP data loss include vascular insufficiency, overcorrection of the deformity, a combination of mild hypotension and overcorrection, and instability causing subluxation, laminar impingement or cord buckling. During deformity correction, the distraction forces stretch the anterior spinal artery leading to loss of intraoperative data. The relatively prompt return of neuromonitoring signals by releasing the correction supports this vascular theory. Temporary stabilizing rods before completing osteotomy can prevent neurologic deficit brought by abrupt instability of the spinal columns. Restoring anterior height restrains excessive shortening. The NMEP signal loss is reversed after suitable maneuvers stressing the importance of timely appropriate intervention.

Electromyographic Techniques

Electromyographic (EMG) technique is advantageous in identification of a specific nerve root injury, allowing early detection of excessive nerve-root traction, mechanical injury, or cortical breach. Intraoperative-evoked EMG monitoring of pedicle screw has been demonstrated to be a simple, safe, and efficacious technique in accurate placement of pedicle screws.⁵¹ Mechanically elicited EMG, also

called spontaneous EMG (spEMG), may be beneficial during the critical phases of surgery (during implant placement, nerve root manipulation), while electrically elicited EMG, also called stimulus-evoked EMG (stEMG) or triggered EMG (trEMG), may be useful during static phases of surgery.⁴⁴ The stEMG principle for identifying cortical breach resulting from placement of pedicle screws is based on resistivity of the different tissues to the flow of electric current. Cortical bone has a high resistivity (low conductivity) to electrical current flow, whereas soft tissue has a low electrical resistivity.⁵² The tip of a monopolar probe is touched to the screw shank or hexagonal port, and the electrical current output is increased by an electrical triggering device. In an intact cortical wall, there is high resistance; however, cortical perforation results to decreased resistance and the flow of electrical current will take the path of least resistance, which is through the breach to the root. As a result, the nerve root will depolarize at a much lower current (<7.0 mA) compared with an intact pedicle (10–12 mA). Subsequently, the root will fire and the peripherally innervated muscle will contract, and this will be recorded as a CMAP.⁴⁴ A positive EMG response at or below a constant-current of <6–10 mA may be an indication for inspection, redirection, or removal of the instrument or implant (Fig. 127.7).⁵¹

Thoracic pedicle screw stimulation is more difficult than lumbar screws; furthermore, T1–6 monitoring results may not be reliable. An abnormal EMG response during a spine procedure may or may not be associated with a clinical deficit,⁵³ while on the contrary, normal EMG response does not insure against lateral breeches. Another limitation is its use in chronically compressed roots. Having an elevated threshold, long-standing motor nerve root compressions will not fire spontaneously or will result in false-positive tests in stEMG techniques. A quiet spEMG of a chronically compressed nerve root does not translate that the root is “safe.” Chronically compressed nerve roots show altered thresholds; thus, must serve as their own control to establish a safe trEMG threshold.⁴⁴ Metabolic conditions, such as diabetes, can also affect outcome results. Paralytic agents cause neuromuscular junction blockade thus producing false-negative results.

Multimodality Monitoring

Different monitoring technique has its own advantage and limitations, one technique alone will not be able to meet

Fig. 127.7: Electromyographic monitoring.

all monitoring needs. No single monitoring technique can assess both motor and sensory pathways; therefore, multimodal spinal cord monitoring has been proposed to improve monitoring reliability and validity.⁵⁴ The utility of multimodality monitoring is stressed and should be considered a standard of care during spinal surgery.²⁸

In the retrospective review of Pastorelli⁵⁵ with 172 spinal deformity patients using intraoperative monitoring either with SEPs alone or combined with TES-MEP showed an overall prevalence of postoperative neurologic deficit of 2.3%. When combined SEP and TES-MEP monitoring were performed, the sensitivity and specificity of neurologic monitoring for sensory-motor impairment was 100% and 98%, respectively. They recommended that combined SEP and TES-MEP monitoring must be regarded as the neurophysiological standard for intraoperative detection of emerging spinal cord injury during corrective spinal deformity surgery. Early detection affords the surgical team an opportunity to perform rapid intervention to prevent injury progression or possibly to reverse impending neurologic sequelae. In cervical spine surgery, the sensitivity and specificity for detecting evolving motor tract injury with TcMEP was 100% compared to 25% sensitivity and 100% specificity with SSEP.⁵⁶

Luk³⁷ did a prospective study comparing the outcomes of different-evoked potential techniques for intraoperative spinal cord monitoring. They compared cortical somatosensory-evoked potentials (CSEP), cortical motor-evoked potentials (CMEP), spinal somatosensory-evoked potential (SpSEP), and spinal cord-evoked potential (SpCEP) on 30 patients. Their results did not demonstrate significant variability in the latencies of each technique however amplitudes showed significant differences between different techniques. Cortical somatosensory-evoked potential was more variable but easy to use, economical, and

noninvasive. Spinal somatosensory-evoked potential is easily interrupted by surgical procedures and loading of spinal instrumentation but is also the most stable and reproducible technique, rarely influenced by anesthesia, and capable of producing relatively large amplitudes for monitoring. Cortical motor-evoked potential is reliable and stable with large amplitudes and easily recognizable waveforms but is difficult to elicit from scalp stimulation. Spinal cord-evoked potential, though easily detected with good signal, monitoring is easily interrupted by surgical procedures. The four techniques complement each other. The study recommends that CSEP and CMEP should be recorded first to assess the waveforms quality. If CSEP and CMEP waveforms obtained are clear and large, then SpSEP and SpCEP are not necessary. Spinal somatosensory-evoked potential or SpCEP can be used as substitutes for CSEP and CMEP, respectively. Spinal cord-evoked potential and CMEP had clearer waveforms of greater amplitude allowing faster detection than CSEP and SpSEP waveforms. Furthermore, SpCEP and SpSEP waveforms were more easily influenced by the surgical procedure. Their conclusion was CSEP and CMEP are recommended for routine monitoring so that both ascending and descending tracts are monitored. If signals are not easily obtained, SpSEP can be substituted for CSEP while SpCEP can substitute for CMEP.

Schwartz⁴⁰ investigated the advantage of monitoring the spinal cord motor tracts directly by recording TcMEP along with SSEP. They concluded that TcMEP are highly sensitive to alterations in spinal cord perfusion either from hypotension or a vascular insult. In addition, changes in TcMEP are detected earlier than changes in SSEP, enabling a more rapid identification of impending spinal cord injury. This has been supported by Vitale et al.²⁰ and recommends combined SSEP and MEP allowing early detection of spinal cord dysfunction in most patients.

A 23-year retrospective study of 3,436 consecutive pediatric orthopedic spinal surgery patients⁵⁷ reviewed different monitoring techniques, including SSEP, descending neurogenic-evoked potentials, TcMEP, and various nerve root monitoring techniques. The combined use of SSEP, TcMEP, descending neurogenic-evoked potentials and EMG monitoring allowed accurate detection of permanent neurologic status in 99.6% and reduced the total number of permanent neurologic injuries to 6 out of 3,436 cases. Combined SSEP and MEP monitoring effectively prevents neurologic injury in most children undergoing surgery for spinal deformity.

It has been reported that NMEPs provide an early warning of impending neurologic deficit well before SSEPs have changed. Thus, it is imperative in these high-risk kyphotic correction cases to have a combination of multimodality and neurologic spinal cord monitoring including some type of motor tract monitoring. Somatosensory-evoked potential data did not change before the loss of NMEP data. Thus, using SSEPs alone, even with a wake-up test, may not provide the early warning necessary to avoid a real neurologic deficit after surgery.⁵⁰

Latencies and amplitudes of SEP in the different stages of scoliosis surgery were compared by Luk et al.,³⁸ showing that the latency values and their percentage variabilities did not significantly differ from each other in different stages of surgery. However, the amplitudes between different stages of surgery showed a statistically significant difference, particularly the decrease in amplitude between preoperation (stage 1) and spine exposure (stage 2). This study shows that there is some variability in the latencies and amplitudes between different stages of scoliosis surgery though still within normal range. Using the decreased amplitude in stage 2 (spine exposure), when there is no risk in injuring the spinal cord mechanically, there were no false-positive readings. This lower amplitude at stage 2 can be used as reference baseline to determine whether SSEP are subnormal at the subsequent stages of surgery and may be a more reliable baseline for monitoring. The difference in amplitude can be attributed to the decrease in the core body temperature and the spinal cord that occurs while the spine was exposed. This can be reversed by warm irrigation of the wound.

It is imperative to determine the baseline in relation to the normal variability to improve the reliability of the intraoperative SEP monitoring.⁵⁸ It is recommended to have a low threshold for defining relevant electrophysiological changes despite the potential for false-positive

results. Rapid intervention can reverse these changes and avoid potentially serious neurologic complications.²⁰

Stagnara Wake-up Test

First described in 1973, this test is used to assess the neurologic function intraoperatively.⁵⁹ The wake-up test is performed after the desired correction has been achieved with temporary reversal of general anesthesia, after which the patient is asked to move the upper and lower extremities. A positive wake-up test was defined when voluntary movement of one or both lower limbs was NOT observed with normal upper extremity function, while a wake-up test is negative when the patient demonstrates normal motor function from all four extremities on command.⁵⁷ It is important to counsel the patient before surgery that she will be asked to move her lower limbs during surgery.

This test interrupts the surgical procedure to allow for the awakening, which is time-consuming and cannot be performed repeatedly during the operation. Therefore, the exact moment when trauma was incurred remains uncertain; it may have been performed long after the injury to the cord.³⁸ This global assessment of the spinal cord function does not provide accurate data concerning subtle weakness, timing or location of the neurologic injury. An early neurologic injury presenting only as motor weakness can also be missed because it is not possible to obtain a true motor strength examination.³⁵ This test should be reserved for patients who are able to understand and follow specific commands and has limited use in patients with intellectual and developmental disability and young age, as they have difficulty following commands and in those with language barriers.^{55,60} It is inappropriate in patients with preoperative weakness because assessment will not be accurate. Other risks in performing this procedure include self-extubation, loss of intravenous access, loss of safe patient positioning on the table, air embolism, and postoperative recollection of event.⁶⁰

The most significant shortcoming of the wake-up test is that it is done at a single time during surgery which is after correction. It assumes then that spinal cord injury cannot occur at any time during surgery. The temporal delay in detecting injury from the time of insult is significant because identification of the particular maneuver, causing the injury is not possible. Therefore, timely intervention is delayed and injury may not be reversible. Manifestation of the injury is not time-locked and may present itself at any time, even after wake-up test is performed.^{40,61}

MANAGEMENT OF INTRAOPERATIVE NEUROLOGIC LOSS

Preoperative Preparation

Risk for neurologic injury starts even before surgery and the surgeon should be well-prepared every step of the way. A thorough understanding of anatomy minimizes direct injury to the neural elements. The pedicle is a constant anatomical landmark for the exiting nerve root, which is located inferomedial to it. The conus medullaris terminates between L1 and L2 in adults; injuries to this may cause bowel, bladder or sexual dysfunction. Normal anatomic variations should be recognized in preoperative studies to modify approach. The incidence of conjoined nerve roots is between 2% and 14%. In approaching the lumbar spine anteriorly, particularly in approaching the L5/S1, be mindful of the hypogastric nerve plexus and sympathetic chain. The hypogastric plexus innervates the seminal vesicles and the vas deferens in males, traumatizing these results into retrograde ejaculation. Injury to the sympathetic chain on the anterior surface of the psoas can cause contralateral foot coldness and increased in warmth on the ipsilateral foot.

The patient's clinical condition is another factor to consider when choosing the surgical approach. It has been reported that the risk of dural disruption in multilevel cervical OPLL is higher in the anterior approach versus the posterior approach. Posterior approach is therefore suggested in this condition provided having a lordotic cervical spine or flexible kyphosis.⁶² Anterior decompression for cervical myelopathy was found to have an incidence of 3.2%,⁶³ and as high as 6.7%⁶⁴ for postoperative C5 radiculopathy. C5 palsy is manifested by paresis of the deltoid and/or biceps brachii muscle, sensory deficits, and/or intractable pain in the shoulders.⁶⁴ Saunders⁶⁵ identified several risk factors after cervical corpectomies, including moderate-to-severe myelopathy, age >60 years, kyphosis, and a wider corpectomy decompression. Functional recovery is generally good, but severely paralyzed cases (MMT ≤ 2 or less) require significant longer recovery time compared to mild cases.⁶⁶

Anterior approach to the lumbar spine is advantageous because it allows direct access to ventral pathology, spares lumbar paraspinal musculature improving postoperative mobility and decreases chronic muscle pain, avoids previous posterior surgical scars, and enables anterior placement of interbody grafts and devices.^{2,67} Posterior lumbar

interbody fusion and transforaminal lumbar interbody fusion allow improved segmental and coronal correction and provide anterior column support, while allowing indirect foraminal decompression and with greater surface area for arthrodesis. However, approach-related neural injury includes trauma to the exiting or traversing nerve root while accessing the intervertebral space.¹

Preoperative discussion with the anesthesiologist in patients with special considerations facilitates patient care. The anesthesiologists can anticipate special procedures such as deformity correction, wake-up tests, and the use of intraoperative monitoring. Halogenated anesthetics affect SSEPs but have little effect on spinal SEPs.⁶⁸ Spinal SEPs are affected by temperature and local anesthetic agents, while cortical SEPs are affected by inhalational and induction agents, local anesthetics, and opioids. However, MEPs are sensitive to inhalational drugs.⁶⁹ Adequate intravenous access should be available and central venous access as well as arterial line to monitor the mean arterial blood pressure are suggested. Consider using fiber optic intubation in patients with severe cervical stenosis to avoid excessive neck manipulation.⁷⁰ Special care should be observed during positioning in patients with high-grade lumbar or cervical stenosis to avoid neurologic injury. Document the preoperative range of motion in cervical spondylotic myelopathy patients. Patient with cervical stenosis should be transferred with the neck in neutral or slightly flexed position. Keep the abdomen free to minimize intraoperative blood loss when positioning the patient prone. Peripheral nerves are at risk for injury during anterior cervical spine surgery from traction or direct pressure on the brachial plexus or ulnar nerve during intraoperative positioning. Keep the extremities well padded. Leads for intraoperative neurologic monitoring should be placed and secured before positioning the patient.

Suffice it to say that to decrease the risk of injury to neural elements, adequate exposure is needed without removing bone excessively that could lead to iatrogenic instability. In using sharp instruments, such as the pituitary rongeur or the burr, be mindful of the neural structures to avoid direct injury. Careful retraction of neural elements after the dura has been freed should be observed, avoiding manipulation of the thecal sac above L2. When removing the flavum, avoid tearing or ripping from the dura. Meticulous hemostasis should be practiced by using bone wax and hemostatic agents, and using drains as needed.

During surgery, it is imperative to maintain adequate mean arterial pressure (MAP > 70–80 mm Hg) to preserve

adequate spinal cord perfusion. It has been demonstrated that spinal cord ischemia may result from prolonged extreme hypotension (MAP < 55 mm Hg), hypoxia secondary to decreased hemoglobin level, or vascular compromise after ligation of segmental vessels in an anterior procedure.⁷ Ideally, the MAP should be maintained at 65–70 mm Hg during exposure and placement of instrumentation.⁴⁰ Inform the anesthesiologist before doing corrective maneuvers to gradually elevate the MAP > 70 mm Hg to maintain cord perfusion during the spinal manipulation and correction.³⁵

Instrumentation should be placed with utmost care and deformity corrected using precise techniques. Malpositioned screws, apart from neuronal injury and pain syndrome, can induce loss of fixation.³ Use of osseous landmark guides the proper starting point in pedicle screw insertion or directly palpates the pedicle through a laminotomy in severe deformity. Inspect for inadvertent perforations, after creating the screw track and after tapping. Radiography or fluoroscopy should be used to assess screw placement and overall alignment after insertion of hardware. Neural elements should be protected during interbody preparation and interbody implant placement. Posterior interbody grafts or cages used in lumbar interbody fusions can displace and encroach on the nerve roots or cauda equina. During posterior lumbar procedures, the wide exposure required for graft insertion increases the risk to traction injury or development of instability.³⁶

Using multimodality spinal cord monitoring decreases the rate of major neurologic deficit by alarming the surgeon of neurologic injury or impending injury so remedial action can be performed to reverse the trauma. Using intraoperative neurologic monitoring such as TcMEP and SSEP appears to be prudent for procedures where there is significant risk of injury to neural structures and in high-risk patients.³⁹ Somatosensory-evoked potential and/or MEP signals must be continuously monitored during surgery, instrumentation, and deformity correction. Once changes are observed, the surgeon must be alerted, and immediate action is imperative. Generally, neural injury is suspected when there is change of >50% amplitude and >10% latency in the SSEP and/or MEP signals. The combined monitoring of sensory-evoked potentials and MEPs during spine surgery decreases the false-negative rates of reporting. Combining MEP monitoring with SSEP in spine surgery⁷¹ is advantageous because more patients can be monitored. Accuracy is increased by complementary

information from two independent systems reducing the risk of false-negative results, and increasing sensitivity in identifying early spinal cord dysfunction.

Once the surgeon is alerted of signal change, he should halt the surgery and investigate the reason for the significant change in signal, undertaking a structured and fairly logical procedure. First determine if there is any technical problem or equipment malfunction. Check the leads and connections that they are secured and in proper position. Stimulation limits might have to be changed and electrodes repositioned. Adjust patient positioning and relieve vena cava pressure. Next, verify anesthetic concentrations with the anesthesia personnel, along with blood loss and mean arterial pressure.⁵⁷ Physiologic factors such as anemia and hypotension, which greatly affect spinal cord perfusion, should be corrected. Optimize the hemodynamic status of the patient (elevate MAP > 80 mm Hg or 20% above baseline values) to improve perfusion pressure to the spinal cord.^{40,72} Most false-positive TcMEP changes occur when the mean systolic blood pressure is too low, thus keeping the mean >80 mm Hg is necessary to eliminate false-positive results. Hypertension might have to be induced to increase MAP, and to do so, the anesthesiologist should start a dopamine drip to raise the MAP. It has been suggested that optimizing hemodynamic conditions should be done before unloading the distraction because mechanical factors (e.g. distraction-induced vasoconstriction, increased spinal cord interstitial pressure) and suboptimal hemodynamic conditions when combined can alter the MEPs.³¹ Furthermore, ensure that the patient's temperature is > 36.5°C (97.7°F) to optimize neuromonitoring. Irrigate the wound with warm saline. Investigate the glucose levels. Other factors to check would include retractor positions and removing intradural packings and explore the wound for direct injuries to the neural elements. Reassess signals after every step because this aids in accurately identifying the possible inciting factor. A wake-up test is recommended to assess the spinal cord function if there is any doubt or with increased risk of postoperative neurological deficits.^{38,73} When suspected spinal cord injury (SCI) occurs, radiographic and/or direct examination of bone graft and hardware should be conducted to confirm the lack of direct spinal cord compression.⁷⁴

The role of steroids remains to be controversial.⁷⁵ Steroids could be administered to patients who have a continued negative wake-up test (absence of motor function) after the release of tension from corrective and distractive

maneuvers.^{40,60} Consider using high-dose methylprednisolone or intravenous dexamethasone.^{4,60,76}

The release of tension or degree of correction should be contemplated if the previously mentioned factors have been looked into and fairly rectified without any signal return. Set screws are loosened and the rod may be removed to lessen the correction. Early removal of instrumentation may increase the possibility of neurologic improvement⁷⁷; however, the stability of the spine has to be ensured to avoid subluxation of the spinal column when the rod is removed. If the removal of instrumentation weakens the stability of the spinal column (i.e. vertebral body resection), the surgeon may be obliged to maintain the existing instrumentation and fuse the spine under the least amount of tension.⁶⁰ The signals are checked promptly after each maneuver, and once the signals return, correction can be sustained by fusing it in situ or one with a lesser correction, or attempt a more modest correction.⁷⁷ Return to baseline of the evoked potentials should be demonstrated before more reduction is attempted. It is also essential to assess for any impingement that would require a more thorough decompression before the repeating any attempts in correction. If signals improved following surgical intervention, no further action was taken. The Stagnara test was used when signals remained degraded despite intervention, or when no apparent cause-effect relationship for the signal loss was found within the surgical procedure.³¹

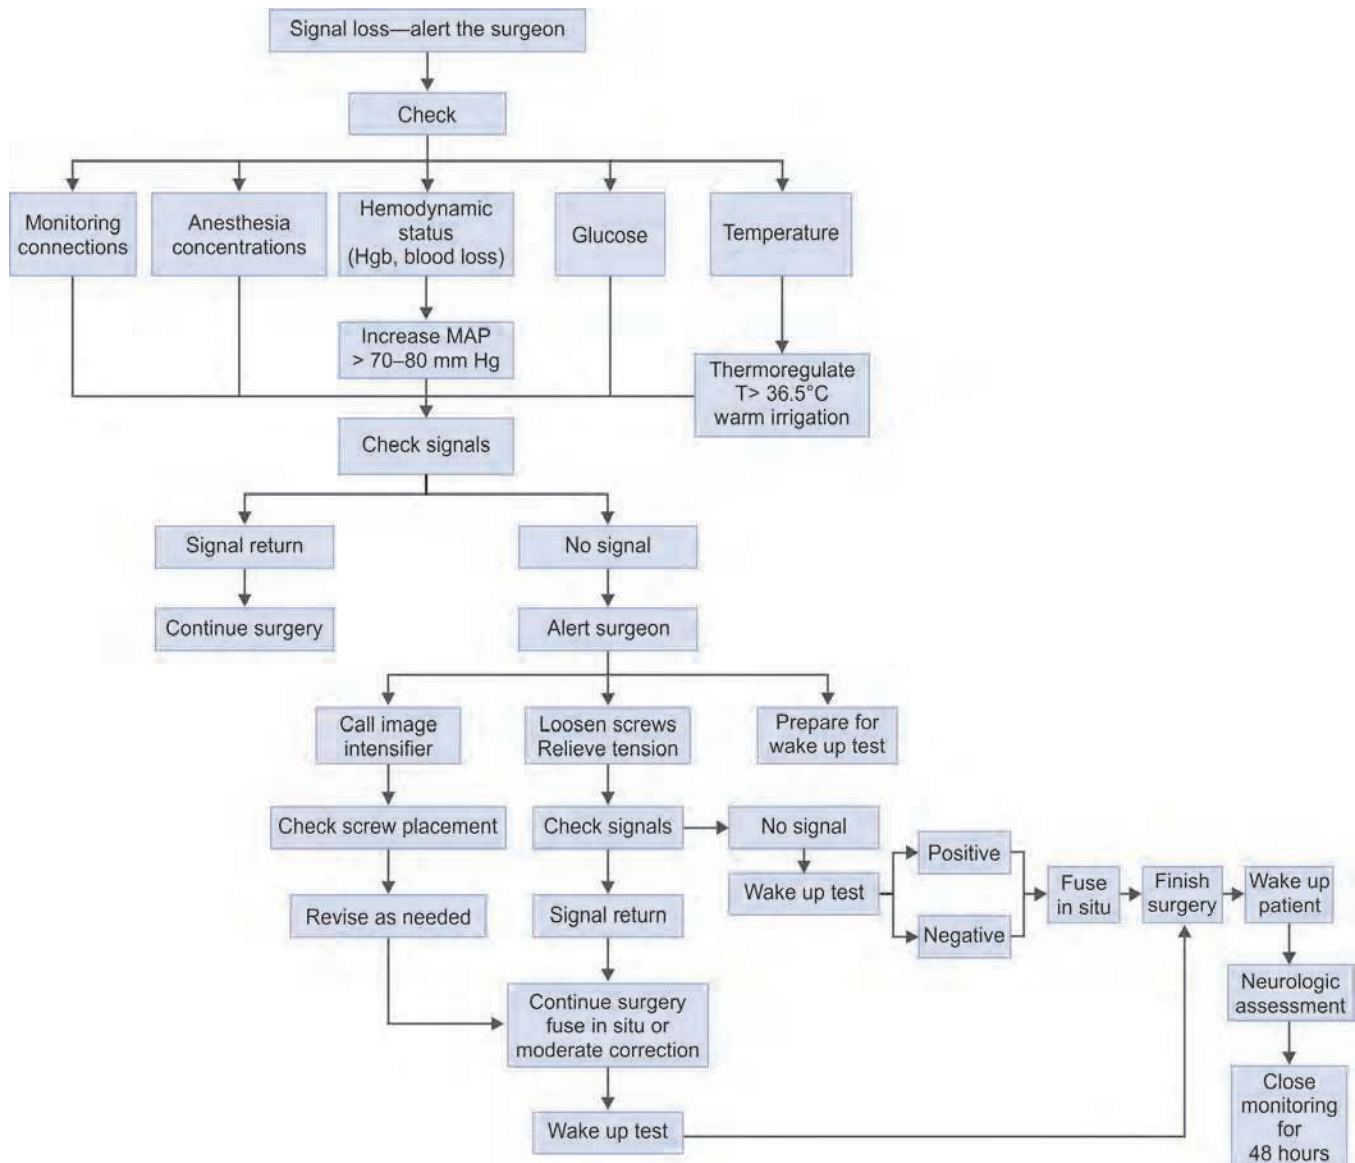

In a report of 275 consecutive patients treated with posterior spinal instrumentation and fusion with intraoperative neuromonitoring (IONM) using SSEP, patients who exhibited significant evoked potentials changes during instrumentation showed return to baseline with immediate removal of the instrumentation with all patients neurologically normal postoperatively.⁷⁸ Similar results have been reported demonstrating no subsequent neurologic deficit after revision of the operative procedure when evoked potentials changed.^{3,79} Another report demonstrated that interventions caused by IONM change reduced true-positive outcomes from 3.1% of those with signal change to 0.12%.²⁸ Therefore, one can surmise that changes in cord function can be reversed when the cause is quickly remedied.³

Pedicle screw malposition was the most commonly identified problem according to a report by Raynor et al.²⁸ Therefore, pedicle screw position should also be closely examined in monitoring change, using image intensifier and removing suspicious screws, and verifying the integrity

of the track by direct palpation using a ball tipped probe. A pedicle screw tip that is past the midline of the vertebral body on PA radiographs suggests a medial pedicle breach.⁸⁰ A small laminotomy may also be performed to evaluate the integrity of the medial pedicle cortex with or without screw removal.⁴ An EMG may be also be used to investigate pedicle wall breach. Any pedicle screw with markedly lower EMG threshold (<60%) compared to the rest of the construct should be assessed because this may indicate a possible pedicle wall breach.⁸¹ A stimulation threshold >15 mA reliably indicates adequate screw position while stimulation threshold between 10 and 15 mA, generally associated with adequate screw position, exploration of the pedicle is recommended. A stimulation threshold <10 mA was associated with a significant cortical perforation in most instances.⁵¹ If there is any breach or malposition, screws are reinserted and position verified using imaging techniques (Flowchart 127.1).

The spinal cord should not be retracted during surgery. Spinal cord tissue is much less tolerant to traction and compression than nerve roots; therefore, even minimal manipulation of the cord may cause profound neurologic consequences. Moreover, the spinal nerve roots are less tolerant to mechanical deformation compared to peripheral nerves. The intradural nerve rootlets are covered by a thin sheath that is permeable to cerebrospinal fluid for nutrition,⁸² while peripheral nerves are protected by epineurium and perineurium making them less susceptible to injury. Traction can substantially reduce nerve root blood flow, causing ischemic nerve root injury resulting in nerve dysfunction.⁸³ Decreased retraction time and tension leads to lower the rate of ischemic injury.

Dural tears, one of the most common iatrogenic injuries, may occur during any spinal procedure in which the dura is decompressed, manipulated, or brought into contact with the surgical instruments. The incidence of dural tear during anterior cervical spine surgery has been reported to range between 2% and 14%.¹ Revision interbody fusion procedures have a higher minor perioperative complication rate, particularly dural tears, than primary procedures.⁸⁴ To avoid dural tears, removal of the ligamentum flavum should be done with utmost care with proper instruments. Direct repair with suture or placement of fibrin glue or other sealant is recommended to prevent persistent CSF leakage and increased risk of meningitis and pseudomeningocele formation.¹ Chang⁸⁵ demonstrated

Flowchart 127.1: Algorithm for intraoperative neurologic loss.

the formation of syrinx when CSF flow in the subarachnoid space was obstructed. There is increase in spinal cord pressure distal to the blockage, and this location corresponded to the preferred site of syrinx formation in adhesive arachnoiditis. He further suggests that surgical procedures, such as shunting, be performed to reduce this pressure gradient. A Valsalva maneuver aids in the identification of a persistent or residual leak. If there is a persistent leak, reinforce repair with muscle or fat grafts sutured over the repair to the dura. Larger defects may require patch grafting with a segment of fascia from the paravertebral muscles.³⁶ Watertight

closure without wound drains is required. Durotomies that occur during minimally invasive procedures are difficult because of the limited exposure and one may have to convert to open techniques to allow repair. Postoperative management of dural tears includes 24–48 hours of bed rest to reduce pressure and allow dural healing. Antibiotics are given to reduce the risk of meningitis. Lumbar drains can be considered in repairs that are doubtful. To reduce intraspinal CSF following surgery, upright patient positioning in the cervical spine, while recumbent positioning is suggested if the leak was in the lumbar region.

Recognizing the cause of IOM signal degradation is critical because it leads to timely use of appropriate and effective intervention. There was good correlation exists between problem recognition, intervention, and data improvement, with intervention leading to signal improvement as a strong indication for a favorable neurologic outcome.³¹

Postoperative Care and Detection of Deficit

Once the patient is awake, immediate evaluation of the neurologic status is warranted before leaving the operating room. Frequent neurological examinations in the first 48 hours after surgery are highly recommended. Postoperative evaluation of patients with new neurologic deficits should include an emergent MRI or CT myelogram to evaluate for neurologic injury and to rule out hematoma or misplaced graft or hardware.¹¹ In patients with postoperative neurologic deficits or leg pain after placement of instrumentation, CT scan is the imaging modality of choice because it accurately demonstrates screw placement. Unsatisfactory screw placement in the setting of new onset leg pain or neurologic deficit is best managed by reoperation to remove or replace the device and to ensure adequate neural foraminal decompression.³⁶

Early postoperative deficit (1–14 days) usually occurs secondary to retained disc fragments after discectomy, postoperative hematoma, pseudomeningocele, herniation of a fat graft or rarely an epidural abscess.³⁶ Early re-exploration is suggested if nerve palsy is complete; however, a more conservative management such as watchful waiting is done if palsy is incomplete. Serial examinations and electrodiagnostic studies at 1 and 3 months are done if deficit is persistent. If there are no signs of recovery at 3 months, explorations are also suggested.

KEY POINTS

- Low risk for neurologic injury in spine surgery but has great impact on patients.
- Preparation of both the patient and surgeon is imperative to decrease the risk of neurologic injury.
- Consider intraoperative monitoring, in particular multimodality intraoperative neurologic monitoring.
- Follow an algorithm in managing intraoperative neurologic loss and do appropriate and timely maneuvers to rectify and possibly reverse the deficit, preventing permanent injury.
- Postoperative monitoring is important since neurologic injury can still occur even after surgery.

OVERVIEW

Complications of anterior and posterior cervical spine surgery could be categorized as general, access related, decompression related, instrumentation related, fusion related and delayed or late complication of postlaminectomy kyphosis.¹ Avoidance of complications require good preparative planning such as having the correct indication for surgery, thorough assessment and preoperative preparation of the patient and acquiring all the necessary imaging, equipment (blood products, neurophysiological monitoring, anesthetic equipment), medical evaluation prior to surgery and adequate personnel familiar with different operating tools. Furthermore, ensuring that as a part of the surgical plan there is a “fall-back” option to which the surgeon can resort if intraoperative events are encountered is very helpful in ensuring a successful outcome.

GENERAL COMPLICATIONS

Anesthesia and Positioning

The incidence of postoperative respiratory compromise after multilevel anterior cervical decompression with or without posterior fusion was reported as 0–14%.^{2–5} Respiratory compromise is a result of upper airway edema due

to anterior soft-tissue trauma or if the patient is in prone position for too long.^{2,4} If the spinal cord is at risk due to instability, the neck muscles are unable to provide the necessary stabilization to protect the cord during manipulation when intubating. Undue force used during laryngoscopy and tracheal intubation may move the cervical vertebrae and jeopardize the spinal cord. In these cases, manual inline axial stabilization and fiberoptic endoscopy is necessary; however, the safest technique available is to perform an awake fiber-optic intubation while ensuring that the patient’s neurological examination remains unchanged.

Hypotensive anesthesia provides surgeons with an easier surgical exposure due to reduced blood loss. However, this blood pressure must be carefully controlled to avoid spinal cord ischemia. Spinal blood flow of at least 65% of baseline is required to maintain physiological integrity of the spinal cord and a 12% decrease in blood flow carries with it the potential for paralysis.^{6,7} Usually, a mean arterial pressure of 65 mm Hg, or 20 mm Hg below baseline in normotensive patients is safe in patients in whom their spinal cord is not otherwise at risk (compressed or manipulated).⁸ Adequate neural perfusion is particularly important in traumatic spinal cord injury due to an already compromised swollen spinal cord. Often, a mean arterial pressure of 85 mm Hg is necessary for perfusion.

Patient positioning is the first responsibility of the surgeon to provide easy surgical access and to prevent pressure areas at bony prominences and to avoid iatrogenic injuries. For posterior cervical approaches, the head and neck must be controlled during turning either by free-hand or via Halo ring or Mayfield tongs. Prone positioning may increase intraocular pressure leading to ischemia, decreased perfusion pressure and blood supply to the retina causing ischemic optic neuropathy and blindness. Injury to the eye can occur as a result of pressure due to the Mayfield headrest or Gardner Wells tongs. Shoulders are pulled distally to facilitate lateral X-ray of the cervical spine and are usually taped to the operating table. The shoulders should not be extended below the coracoid process to avoid brachial plexus compression. Neurological deficit can occur during improper positioning such as brachial plexus injury. Thus, the shoulder should not be abducted beyond 90°. In prone position, the shoulders should be flexed, internally rotated and minimally abducted to avoid thoracic outlet obstruction. The radial nerve may also be injured if the arm hangs over the edge of the operation table. Injury to the common peroneal nerve can occur if the lower extremities roll into abduction with external rotation. Pressure necrosis of skin over the sternum, breasts, iliac crests and knees is more common in prone positioning. Adequate padding under pressure points can prevent skin breakdown and peripheral nerve compression.

Bone Grafting

Up to 2.5% of iliac crest bone-grafting procedures have been associated with long-term harvest site pain (3 months).⁹ Superficial nerve injury following iliac crest bone-graft harvest is not commonly discussed but may occur more frequently than appreciated. Ilioinguinal neuralgia can occur from retraction of the abdominal wall where the nerve is pinched between the retractor and the iliac crest. With posterior iliac crest bone graft harvest, care must be exercised to prevent injury to the superior cluneal nerves, which cross just lateral to the posterior superior iliac spine and supply sensation to the superior two-thirds of the buttocks. Careful soft tissue handling such as reduced stripping of pelvic muscle or thigh musculotendinous attachments from anterior thigh muscles to the iliac crest, protection of sensory cutaneous nerves and less subperiosteal stripping can help reduce postoperative donor site pain. Poor donor site handling can lead to hematoma or seroma formation and subsequent infection but these complications can usually be treated by antibiotics alone.

Watertight closure of wounds can prevent fluid from entering the subcutaneous space thereby avoiding seroma formation. A deep drain should be used in expected deep hematoma formation to drain it and avoid infections. However, there is limited evidence for drain use as one prospective randomized study showed no differences in the occurrence of wound complications (10%) even with a suction drain.¹⁰

Anterior iliac crest bone graft harvest has risk of injury to the lateral femoral cutaneous or ilioinguinal nerves due to direct injury, retraction, fracture, or subfascial hematoma. Incisional hernia is a rare complication (0.5%) that occurs when bowel protrudes through the osseous defect in the ilium after an inadequate abdominal musculature closure.¹¹ Dissection limited to the outer table of the pelvis with minimization of abdominal and pelvic muscle attachment stripping can help prevent herniation. Avulsion fractures of the anterior superior iliac spine can occur after graft harvest is performed too far anteriorly along the crest and occurs with forceful contraction of the sartorius muscle and/or tensor fasciae latae. In order to reduce the risk of this complication, many authors have recommended that the anterior iliac crest harvest site should be >3 cm posterior to the anterior superior iliac spine.^{9,12,13} Avulsion has been shown to be more frequent with bicortical and tricortical anterior superior iliac spine grafts than with unicortical grafts.¹²

The superior gluteal artery is the most common vascular injury associated with posterior iliac crest bone graft harvesting and is usually injured by a dislodged retractor or osteotome. After transection, the superior gluteal artery frequently retracts into its intrapelvic position behind the sacrosclatic notch and is difficult to approach posteriorly without removing bone from the notch. Direct ligation hence requires turning the patient supine and for exploration through an anterior retroperitoneal approach, or more commonly an urgent trip to the angiography suite where embolization can control the bleeding. Ligation and embolization do not carry significant sequelae such as muscle necrosis or ischemia due to good collateral anastomosis. Prevention of injury requires careful assessment of the safety boundaries. Caudal limit of harvesting should be the inferior margin of the origin of the gluteus maximus at the area of the posterosuperior iliac spine. Retractor placement in the sciatic notch should be avoided and the osteotome should be directed cephalad and away from the sciatic notch.

In the posterior superior iliac spine, if graft is harvested too far posteriorly, the sacroiliac joint can be inadvertently

breached or the posterior sacroiliac ligaments may be compromised, leading to sacroiliac joint instability, pain, and arthrosis. A positive Trendelenburg gait with stance phase pain may occur with over-stripping of the hip abductor attachments to the ilium.

Minimally Invasive Surgery

Despite the advantages of reducing muscle retraction, blood loss and postoperative pain, the limited visualization associated with minimally invasive surgery may lead to unique complications. Radicular injury from manipulation in a tight cervical neural foramen or direct mechanical spinal cord injury during dilation or decompression can occur. Inadvertent nerve injury can occur during insertion of the blunt dilator and it should be inserted with fluoroscopic imaging to prevent it from entering the interlaminar space. Dural tears are more common and has been reported to occur in 1.6-6.6% of procedures.¹⁴⁻¹⁷ The dura could be injured during drilling and complications such as epidural hematoma, progressive quadriplegia, C5 nerve palsy could occur. With dural injury, repair is more difficult with limited access and exposure provided by the small tubular retractor.

For minimally invasive anterior odontoid screw fixation, postoperative hematoma, dysphagia, hoarseness, vascular or neural injuries can occur. Transoral approaches can lead to infections, pharyngeal wound breakdown, meningitis, vertebral artery injuries and cerebrospinal fistulas. Schaefer et al. showed that 23.6% of screws caused pedicle wall perforation, most causing lateral wall perforation (76.4%).¹⁸ The incidence is highest in C3 and C5 followed by C4, and 7 of 72 screws (9.7%) caused narrowing of the transverse foramen of >25%.¹⁸ One must always be cognizant of the potential risk to the esophagus when using drills and other instruments through an anterior cervical approach.

Wound Infection and Discitis

The incidence of postoperative wound infections in anterior cervical discectomy and fusion is very low and is estimated to be between 0.1% and 1.6%.¹⁹ Postoperative infection usually presents as pain. Fever, chills and night sweats can also occur in more advanced presentations. Local wound changes such as erythema or drainage can also occur. In anterior cervical procedures, patients may present with painful swallowing due to a retropharyngeal collection. Epidural abscesses may cause neurological

complications without treatment. Infectious organisms can also tract into the disc space. Long-term prognosis of discitis is generally good at 90% of patients being pain-free and 75% of patients developing spontaneous bony fusion or stable fibrous union within 2 years of diagnosis of infection.²⁰

Surgical time correlates with the bacterial numbers found in the wound. More than 10⁵ organisms can be found in surgical wounds after 5.7 hours,²¹ and operative times >3 hours increase risk of infection.²² Meticulous soft tissue dissection, staying in avascular planes, avoiding the creation of large flaps and potential dead spaces, frequent release of retractors, careful hemostasis and frequent irrigation can help reduce infection.

Culprits in acute infection are usually gram-positive cocci including *Staphylococcus aureus*, *Staphylococcus epidermidis* and β -hemolytic streptococci.²²⁻²⁴ *Klebsiella*, *Escherichia coli*, *Pseudomonas*, *Aerobacter* and *Proteus* are possible gram-negative species commonly present in intravenous drug users. Delayed or chronic infections are usually caused by skin flora of low virulence such as *Propionibacterium*²⁵ and *Diphtheroids*.²⁴

ACCESS RELATED

Surgical Exposure in Anterior Surgery: Dysphagia, Dysphonia and Neck Soft Tissues

Recurrent Laryngeal, Superior Laryngeal and Hypoglossal Nerve Injuries

Reported rates of vocal cord paralysis range from 0.07% to 11%, and the incidence of permanent paralysis ranges from 0.15% to 3.5%.²⁶⁻²⁸ Most vocal cord paralysis is transient lasting for weeks to months. Causes of injury include direct surgical trauma, nerve division or ligature, pressure, stretch-induced neuropraxia, and postoperative edema. Of these, prolonged pressure on the nerve is the most likely cause that decreases mucosal and neuronal capillary blood flow and increases risk of nerve injury.

Careful dissection with proper retractor placement under the bodies of the longus colli muscles and away from the tracheoesophageal groove can prevent injury to the recurrent laryngeal nerve. Longus colli muscles should be elevated cleanly without shredding them to maintain a firm anchor point for retractors. Sharp-toothed retractor blades are advised as they have better anchorage. Blunt tooth blades easily slide anteriorly to compress the trachea

or esophagus medially and the carotid artery laterally. Intermittent release of retraction can also prevent injury. The pressure exerted by the retractor is also important.

The endotracheal tube accounts for 11.2% of recurrent laryngeal nerve paralysis.²⁹ The shaft of the tube can impinge on the lateral wall of larynx, compressing the endolaryngeal portion of the recurrent laryngeal nerve, as it transverses submucosally to enter the vocal cord musculature. Releasing the cuff pressure to deflate the balloon can allow the tube to shift away from the inner laryngeal wall. The cuff can be reinflated to just-sealed pressures. Laryngeal displacement against the endotracheal tube after retractor placement should also be avoided.

Patients may complain of difficulties in singing high notes with superior laryngeal nerve injury. This nerve (C3-C4) can be damaged via an anterior approach to the cervical spine. Hypoglossal nerve injury during dissection of the anterior triangle of the neck at C2-C4 occurs up to 8.6%.³⁰ The nerve is especially at risk in high retropharyngeal approaches to the upper cervical spine where the nerve may traverse the field and may appear to resemble a large blood vessel. Postoperative diagnosis is also difficult as palsy causes dysphagia and dysarthria, symptoms associated with esophageal or recurrent laryngeal nerve injury.

Esophageal Injury

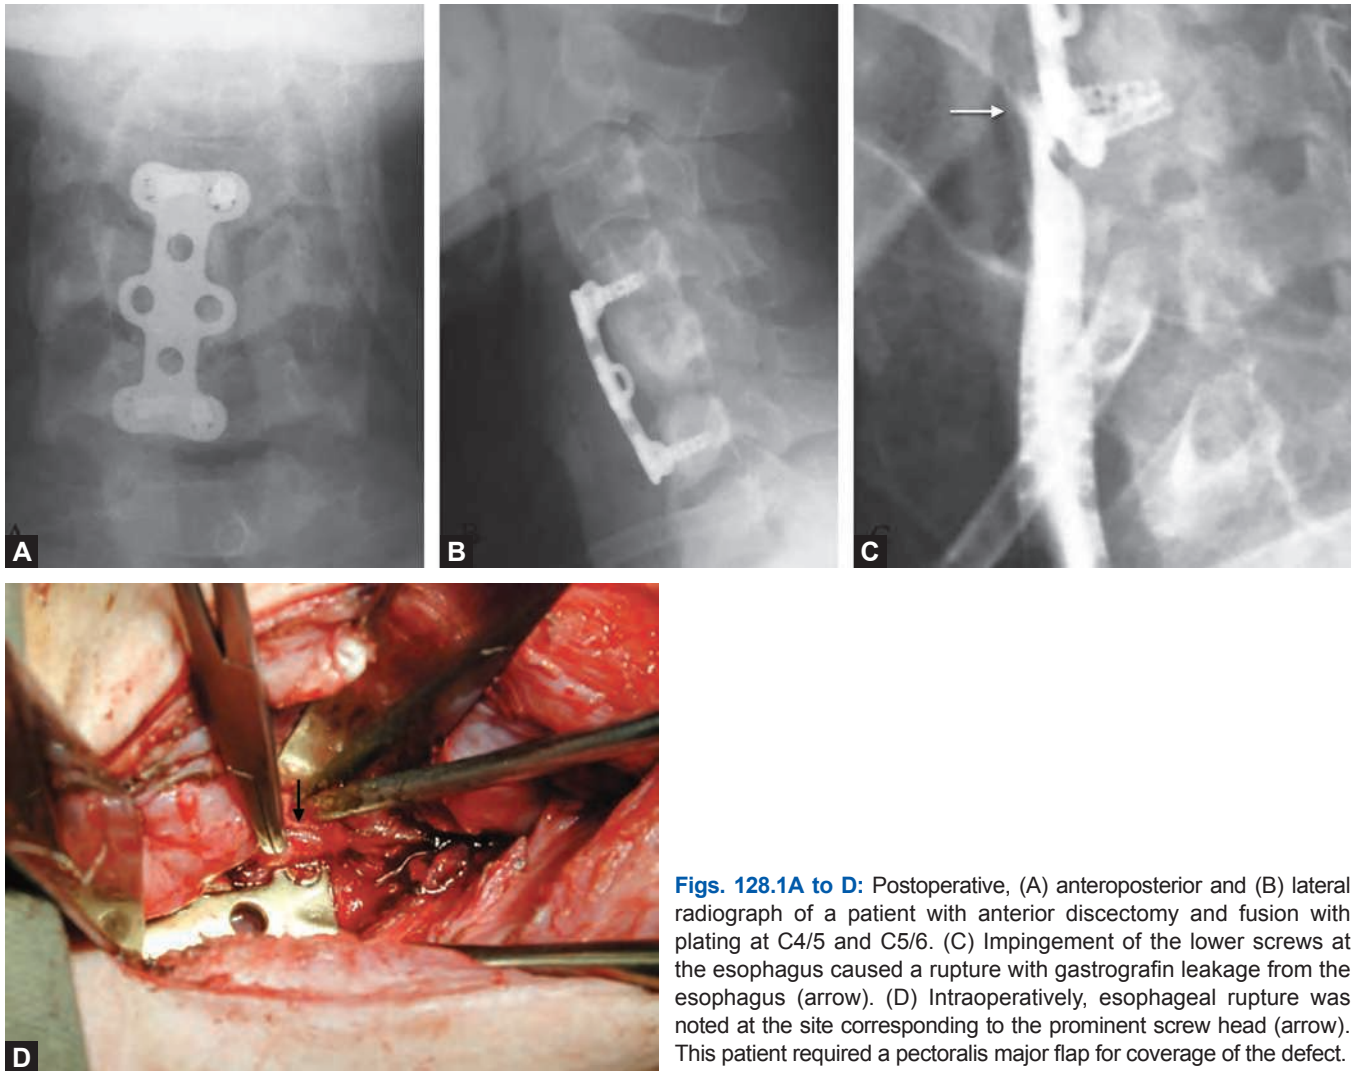

Iatrogenic dysphagia is usually transient with quoted postoperative incidence of 9.5%.¹⁹ Intraoperative retraction of the esophagus is the most common cause of postoperative dysphagia due to ischemia of the pharyngeal/esophageal wall due to retractor blades, leading to reperfusion trauma with edema and swelling. Thus, intermittent release of the retractors can avoid injury to the esophagus. Other causes of dysphagia include postoperative swelling, hematoma, infection, neurological injury to pharyngeal plexus, superior laryngeal nerve or recurrent laryngeal nerve, scar formation around cervical plates and bone graft dislodgement. In prolonged cases, videofluoroscopic swallowing study can be used to determine swallowing integrity. Reduced pharyngeal wall movement, impaired upper esophageal sphincter opening, incomplete epiglottic deflection and postswallow residue in the vallecula, pyriform sinuses and posterior pharyngeal wall can be observed on swallowing studies or with direct video endoscopy.³¹

Esophageal perforation (Figs. 128.1A to D) has an incidence of 0.2–1.15%.^{28,32,33} To avoid the complication, blunt finger dissection below the superficial cervical fascia can

reduce the risk. Proper retractor placement can mobilize the esophagus away from the operative field to prevent injury. The region of the esophagus that is most at risk of perforation with instrumentation is the cricopharyngeal region of the cervical esophagus, where the posterior esophageal mucosa is covered only by a thin fascial layer.³⁴ Delayed perforations after surgery are mostly related to direct erosion of the esophagus by bone, cement, hardware and screw backout or migration.³⁵ Methylene blue is a good tool that can check for the site of perforation. It should be injected into the oral-pharyngeal tube to identify any perforations. Complications arising from esophageal perforations such as wound breakdown, malnutrition, mediastinitis, esophageal stricture, osteomyelitis, pneumonia, prevertebral or retropharyngeal abscess and tracheoesophageal fistulas can result in high morbidity.³³ Mortality is as high as 15–30% and may be >50% if treatment is delayed.^{32,33} Neck pain and crepitus should raise alarms for esophageal perforation and secondary infection. Other symptoms include dysphagia, hoarseness, aspiration, fever, leukocytosis and tachycardia. Lateral plain films of the neck can show subcutaneous emphysema, widening of retropharyngeal or retroesophageal space due to edema or fluid collection, presence of prevertebral air, and migration of the internal-fixation materials. Contrast pharyngoesophagography, flexible fiberoptic endoscopy and computed tomography are other useful diagnostic tools to detect location of perforation and extension of extravasation. Endoscopy can show the site of perforation and computed tomography scans detect abscess and any graft displacement. Common organisms involved in infections postesophageal perforation are *Streptococcus*, *S. aureus*, *Pseudomonas*, *Bacteroides*, anaerobic gram-positive cocci and *Candida albicans*.³³

Vertebral and Carotid Artery Injuries

Injury to the vertebral artery ranges from 0.3% to 0.5%.^{36,37} The uncinate process is an important bony landmark that signifies the lateral border of the spinal canal, and the medial uncovertebral joint should be used as the lateral extent for dissection or drilling. Ventral decompression can usually be carried out to a width of 18–20 mm. Extensive lateral procedures such as decompression of uncovertebral joints or neural foramen, lateral disc removal, posterolateral corpectomy, lateral placement of instruments can all cause injury to the vertebral artery. The artery is most susceptible during surgery anterior to transverse foramen of C7 or during lateral decompressive maneuvers

Figs. 128.1A to D: Postoperative, (A) anteroposterior and (B) lateral radiograph of a patient with anterior discectomy and fusion with plating at C4/5 and C5/6. (C) Impingement of the lower screws at the esophagus caused a rupture with gastrografin leakage from the esophagus (arrow). (D) Intraoperatively, esophageal rupture was noted at the site corresponding to the prominent screw head (arrow). This patient required a pectoralis major flap for coverage of the defect.

from C3 to C6. The longus colli muscles and uncovertebral joints are structures labeling for a secure midline dissection during cervical discectomy or corpectomy.

Some patients may remain asymptomatic due to adequate collateral circulation but others will have devastating vertebrobasilar ischemia or fatal bleeding and vascular embolic complications. Injury to carotid artery is a result of improper and excessive retraction or inadvertent laceration with scalpel or other instruments. Prolonged pressure against the carotid artery can cause thrombosis or cerebral ischemia. Manipulation can also dislodge plaques, causing intracranial embolus. Pollard et al. showed by duplex ultrasound that 14% decrease in cross-sectional area occurs with placement of retractors that reaches 30% at the end of surgery.³⁸

Tracheal Injury

Tracheal injury is life-threatening and can result in tension pneumothorax, mediastinal emphysema and esophageal prolapse into the tracheal lumen leading to acute asphyxia, sepsis and mediastinitis.³⁹ There is also a chance of tracheal stenosis formation.

Thoracic Duct Injury

Thoracic duct injury can occur during left-sided neck dissection. The thoracic duct can be identified, as it enters the dorsal aspect of the subclavian vein and should be protected. Injury results in chylorrhea and postoperative skin flap erythema and edema may be the first indication of a chylous fistula.⁴⁰ Chronic loss of chyle can cause metabolic derangements secondary to depletion of fluid,

electrolytes and protein, and also decreased immune status by peripheral lymphocytopenia. Patients may have progressive weakness, dehydration, and peripheral edema.

Sympathetic Chain Injury

Cervical sympathetic chain injury is rare (4.2%).²⁷ Injury causes ipsilateral Horner's syndrome. The cervical sympathetic chain is located between the carotid sheath and longus colli muscles in the midcervical region. Excessive lateral retraction or extensive dissection of the longus colli muscles from midline can cause injury.

Pharyngocutaneous Fistula

Pharyngocutaneous fistulas are rare complications of anterior spine surgery with occurrence of <0.1%.⁴¹ Perforations may occur as direct trauma to the esophagus during dissection, decompression of the spine with a high speed burr or fixation of the anterior cervical spine.

Revision Surgery

In revision surgery with the scar formation, greater diligence is required during dissection. Up to 10.5% of patients have transient recurrent laryngeal nerve palsy in the literature.⁴² Esophageal injury may carry a higher risk in revision surgery due to the difficult dissection, previously established esophageal dysmotility and scar tissue.⁴³ In revision anterior cervical surgery, it is recommended that the exposure be performed on the same side as the prior surgery. Patients may have a subclinical recurrent laryngeal nerve injury from their index surgery and if a contralateral approach is performed, then there is the risk of bilateral nerve injury, an extremely morbid complication.

Posterior Surgery

Ossified Posterior Longitudinal Ligament

In surgery for ossified posterior longitudinal ligament (OPLL), the reported postoperative incidence was 2–10% for quadriplegia and was 5–17% for root injury (usually involving C5).⁴⁴ An anterior approach is required to directly remove the ossified ligament but has a high risk of dural tear, bleeding from epidural venous plexus and spinal cord injury. Dural tears can be avoided if the anterior ossified lesion is left alone, since it is usually adherent to the dura mater. Anterior decompression for OPLL requires a more

lateral decompression as the OPLL expands laterally at the intervertebral disc level. This also carries risk of injuring the vertebral artery if exploration is lateral to the uncinate process.

Cervical Myelopathy

Woods et al. showed that laminectomy carries with it a greater loss of cervical lordosis and higher tendency to develop junctional kyphosis as compared to laminoplasty when applied for the treatment of cervical myelopathy.⁴⁵ Diminution of range of motion of the neck and increased neck pain are noted in almost all series with a mean loss of 50% of cervical range of motion in Hirabayashi-type laminoplasty.^{46–48} Yonenobu et al. studied 384 patients with cervical myelopathy and found 3.4% incidence of early postoperative C5 nerve root deterioration and 2% incidence of early postoperative spinal cord dysfunction.⁴⁴ Segmental (C5) root level motor palsy is relatively common after cervical laminoplasty with an incidence of 5.5–12% and results in deltoid and biceps weakness.^{49,50} Palsies are motor-dominant but sensory and radicular pain are also possible. C5 dysfunction can occur immediately to 20 days after operation.⁵⁰ Recovery usually occurs over weeks to months but has been reported to take as long as 6 years.⁵¹ The cause is likely due to nerve root traction as the decompressed cord floats posteriorly. The C5 root has a direct, short course with little redundancy, as it exits the spinal cord. As the spinal cord drifts posteriorly after laminoplasty, tethering of the C5 root may occur and stretched beyond its limits of tolerance. C5 is also at the apex of lordosis, so the postoperative spinal cord shift and root traction is greatest at that level. The deltoid is innervated by a single root and C5 nerve root dysfunction has a profound effect on function. Prophylactic C5 foraminotomy may be required in these cases.

Spring-back closure after laminoplasty (Figs. 128.2A and B) has a reported rate of 40% by Mochida et al.⁵² Lee et al. found that at 6 months postoperatively, the AP diameter increase after surgery and opening angle (angle between line connecting medial end of bilateral facet joint and the line connecting the bilateral end of the opened lamina) was reduced by approximately 10% after open-door laminoplasty was performed.⁵³ For double-door laminoplasty, postoperative migration of the cervical spinal cord between the split laminae has been known to cause worsening myelopathy. Plating has not been proven to hold open the hinge in open-door laminoplasty.

Figs. 128.2A and B: Axial computed tomography scans showing (A) hinge fracture (arrow) after laminoplasty and (B) spring back closure.

■ DECOMPRESSION RELATED

Injury to Spinal Cord and Nerve Roots

Injury to the spinal cord can occur during patient positioning, decompression, fusion, fixation or closure. The overall incidence of neurological complications have been reported as 0.18%⁵⁴ and increases with correction of severe cervical kyphosis (2.6%).⁵⁵ The most common etiology is epidural hematoma (0.07%), inadequate decompression (0.04%), vascular compromise (0.03%), graft/cage dislodgement (0.02%) and surgical trauma (0.02%).⁵⁴ Posterior surgery is usually riskier due to sublaminar, interspinous wiring and hooks, lateral mass screws, and pedicle screws. Direct injury to the spinal cord in anterior decompression is rare but may occur in the presence of significant stenosis. Injury is usually caused during osteophyte removal with Kerrison rongeurs or by a drill. Often this complication is not detected until postoperatively. Meticulous hemostasis, adequate illumination and visualization, experience and proper technique are important to avoid this complication. Injury to the spinal cord could also be caused by tapping the bone graft into place after discectomy. Proper appropriate size and shaping of the bone graft and tapping it in place with proper depth and height can avoid bone graft extrusion. Adequate hemostasis can prevent epidural hematoma.

Late postoperative neurological complications can be avoided in posterior reconstruction surgery for cervical

kyphosis correction by prophylactic foraminotomies in the presence of foraminal stenosis, avoiding excessive correction of cervical kyphosis exceeding 9.7° per segment, and avoiding kyphosis correction at C4/5 which causes a most dramatic posterior shift of the spinal cord at the C4/5 segment leading to C5 palsy.^{55,56}

Dural Tear, Cerebrospinal Fluid (CSF) Fistula, and Pseudomeningocele

The risk of durotomy during laminectomy is quoted as 0.3–13% and up to 18% with revision surgery.^{57,58} Risk factors can include old age, thin dura due to chronic compression, ossification of the ligamentum flavum, synovial cysts, scar from prior surgery and surgeon inexperience. Incidental durotomy can present as postural headache, nausea, vomiting, dizziness, photophobia, tinnitus and vertigo but are typically asymptomatic. Symptoms are caused by intracranial hypotension leading to traction on the supporting structures of the brain. CSF leaks can result in inadvertent intraoperative durotomy and may lead to meningitis and brain abscess. The ligamentum flavum and posterior longitudinal ligaments are helpful barriers during decompression of the dura and these soft tissues should be carefully elevated. Persistent CSF leakage is associated with formation of CSF fistulas or pseudomeningoceles. Reported rates of dural tears and cerebrospinal fistula formation after anterior cervical corpectomy vary from 0% to 8.3% and may be as high as 32% in the presence of OPLL.⁵⁹⁻⁶²

■ INSTRUMENTATION/IMPLANT RELATED

Cervical Traction

Local complications of cervical traction include calvarial pin penetration into the dura, pin tract infection, brain abscess, meningitis, propagation of skull fracture, loss of pin fixation, hanging weight complications, arterial injury, missed distraction injury, overdistractive, traction-related disc protrusion, misapplication of pins leading to canal compromise and fracture malalignment. Systemic complications are due to prolonged bed rest include pneumonia, global neurological compromise, thromboembolism, sepsis and decubitus ulcers.

Intracranial pin penetration is rare and is usually associated with falls, overtightening of pins, prolonged halo use, poor patient compliance and improper pin placement. Garfin et al. reviewed 179 patients with halo insertion and reported pin loosening in 36%, pin-site infection in 20%, pin discomfort in 18%, cosmetically disfiguring scars in 9%, nerve injuries in 2% and dural penetration in 1% of patients.⁶³ Pediatric patients have more complications up to 68% with most being pin-site infections.⁶⁴ Due to the relatively thin skull in children, many authors have recommended multiple pins (6–8 pins), special pin designs,⁶⁵ well-calibrated torque wrenches⁶⁶ and lower insertion torques (4–6 in-lb) to prevent skull penetration.⁶⁷

Loss of fracture reduction or spinal alignment may be caused by pin loosening. Failure usually occurs at the pin-bone interface and may lead to neurological compromise. Thus, regular recalibration and replacement is necessary. Loosening of pins is also common with infection and these pins should not be retightened with risk of inner skull penetration. Penetration and pin site infection can lead to brain abscess or meningitis, which is associated with a mortality rate of 24%.⁶⁸ Injury to the temporal artery can also occur from traction pins due to direct laceration or pin site invasion. Ideally, the pins should be placed at the thickest part of the skull bone just above the external auditory meatus. The area directly anterior and superior to ear tragus should be avoided.

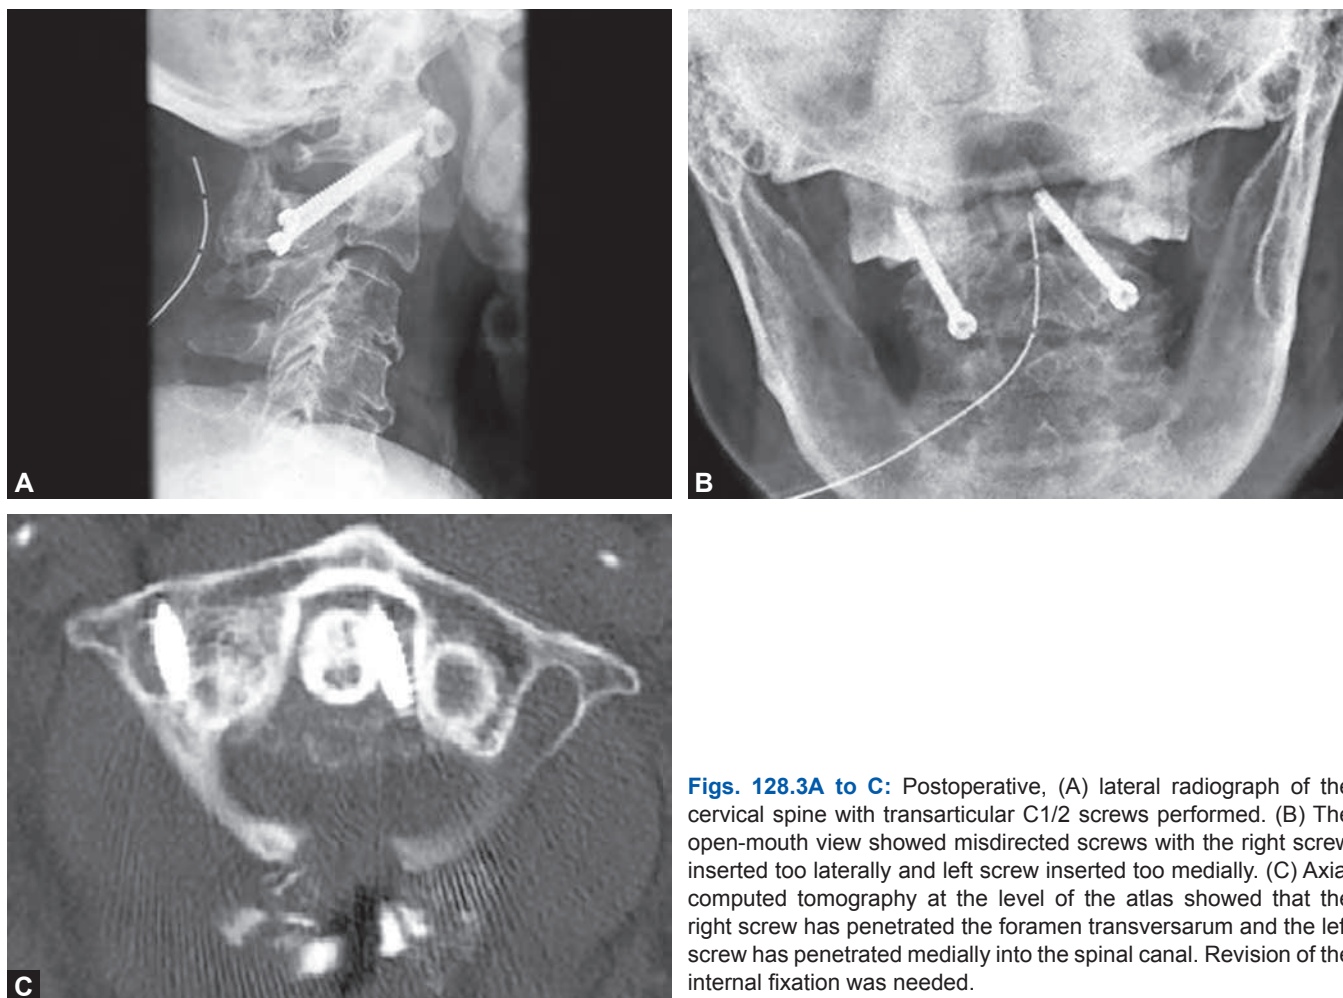

In cases of occipitocervical dislocations, odontoid fractures, ankylosed spine, hyperextension and distraction injuries, overdistractive must be avoided. Overdistractive may cause cranial nerve injuries (abducens, glossopharyngeal, vagus, hypoglossal) with an incidence of 0.07%.⁶⁹ Causes

include neuropraxia injury, ischemia due to edema, direct bony compression or stretching or kinking of the nerve. In patients with ligamentous laxity, other complications include focal cervical kyphosis (16%), loss of normal cervical lordosis (35%) and atlantoaxial subluxation >3 mm (20%).⁷⁰ This is explained by overdistractive and tensioning of the musculoligamentous element stretching beyond its elastic limit.

Screw Fixation

Anterior fixation has higher rates of technical complications (17%) such as loosening of screws or implant, implant cutout, secondary loss of reduction, incorrect reduction, malpositioning of implants, or abandoning the technique intraoperatively as well as need for revision surgery than does surgery performed with posterior fixation (8%).⁷¹ Screw malposition varies from 0% to 4% in the atlas and 0% to 7% in the axis.^{72–74} Transarticular C1/2 screws or Magerl screws in addition have complications of vertebral artery injury, neurological deficit or inadequate bony purchase (Figs. 128.3A to C). Vertebral artery injury is one of the most dangerous complications of screw fixation and is usually due to incorrect cervical pedicle screw entry points with vertebral artery injury. Iatrogenic vertebral artery injury has an incidence of 1.3–4% for Magerl fixation⁷⁵ but fortunately the risk of neurological deficit after injury is only 0.2%.⁷⁶ Mortality, however, is greatly increased if both vertebral arteries are injured. Neo et al.⁷⁷ showed that 84% of screws showed lateral deviation that can lead to violation of the transverse foramen and vertebral artery injury. Current trends include the use of computer-assisted navigation systems that can improve screw trajectory. Ludwig et al.⁷⁸ reduced their perforation rate to 24% and Richter et al.⁷⁹ reported only 3% of screws perforated the pedicles. Medial perforation due to screw insertion seldom cause injuries to the spinal cord because of the wide space between the cord and medial wall of the pedicle.

Subaxial lateral mass screws have a risk of nerve root injury (1.3%) and lateral mass fracture.⁸⁰ Direct root injury during lateral mass screw insertion can be avoided with fluoroscopic control. Screws with a sagittal angulation of <15° are associated with a risk of screw thread impingement on the exiting nerve root (Figs. 128.4A to C).⁸⁰ Screw holes with axial trajectories >30° lateral to midline usually cause no neurological harm but have a risk of lateral mass fracture (1.6%) or screw cutout (1.3%).⁸⁰ Screws placed too medially can cause injury to the vertebral artery.

Corpectomy

The overall morbidity risk associated with corpectomy is quoted as 11–27%, most commonly caused by postoperative dysphagia, hematoma and recurrent laryngeal nerve palsy.^{81–84} Despite the high rate of complications, the mortality rate has been reported to be only 0.1%.¹⁹ Corpectomy has a higher risk of graft-related complications than discectomy including graft migration, strut graft dislodgement, infection and pseudarthrosis.⁸⁵ Other complications include graft pistoning, mortise penetration, failure of the internal fixation device with undesirable deformity or irritation or injury to surrounding vital or neurological structures. Late causes of failure include graft fracture, collapse or subsidence.

Most graft dislodgement occurs within 24 hours postoperatively. Wang et al. studied 249 patients over a 25-year period and found that graft migration rates increased with more levels of fusion (odds ratio of 1.65 for having a displaced graft with each additional level).⁸⁶ Most dislodgements occurred at the C6 level and extension to C7 level (14 of 16 patients) and 5 of these patients required revision surgery.⁸⁶ The likely cause was the junction between cervical lordosis and kyphotic angulation of the sagittal inclination at the cervicothoracic junction, causing increased stress at the graft endplate interface and higher probability of graft extrusion. If the posterior elements are deficient such as postlaminectomy, compression and shear loads through the strut graft are greater increasing the likelihood of failure with graft fracture, subsidence and dislodgement. Supplemental external immobilization with halo vest can be given to theoretically increase the rigidity of the construct and decrease the chance of cage dislodgement especially in long fusions. Partial dislodgement may be closely observed but total dislodgement require another operation, as there is risk of esophageal irritation or penetration with subsequent mediastinal infection. Graft collapse commonly occurs with osteopenic bone. Subsidence and mortise penetration occurs with loss of graft height or penetration into the endplate at the graft-vertebral junction. This may result in kyphosis or loss of structural integrity, leading to sagittal imbalance and muscle spasms. Neurological compromise can even occur with the spinal cord pulled against the apex of the kyphotic deformity. To combat these graft migrations, an additional cervical buttress plate may be indicated.

Anterior plating decreases local motion at the corpectomy site and improves the stability of the construct. However, the center of rotation will be shifted to anterior surface of the spine where the plate is located. Any

subsidence of the strut graft will transfer all compressive loads to the plate leading to failure. The site of failure occurs most commonly at the lower graft junction often with plate and strut graft dislodgement. Dynamic plates theoretically allow continued contact between the graft and the endplate after graft subsidence and improve the chance of obtaining fusion by compressive load on the graft. However, results are controversial with reports of higher nonunion rates with dynamic plates (16%) versus static plates (5%) due to failure of angular motion between screws and plates.⁸⁷

Posterior Occipitocervical Instrumentation

In occipitocervical instrumentation, precise insertion of the occipital screws is crucial to prevent complications. Any screws inserted cephalad to the superior nuchal line can injure the transverse sinus. Loosening of screws is noted in 4.2–7% of cases and rates of dural tears during drilling of the occiput and screw placement range from 0% to 4.2%.^{88,89} For wire-based fixation, dural laceration can occur during drilling of the occipital burr holes or recoil of the wiring with reported rates of 25–28%.^{89,90} Dural laceration leads to CSF leak but screw placement usually is sufficient to halt a CSF leak. Late complications of occipitocervical fusion can include pseudarthrosis (6%) and adjacent level degeneration (7%).⁹¹

Cervical Disc Arthroplasty

General complications are similar between fusion and disc replacement. Although there is a higher rate of adjacent disc degeneration in the fusion group, there is no difference between the two groups in terms of revision rate up to 2 years of follow-up.⁹² There are only two studies that demonstrate a marginal but clinically questionable benefit of disc replacement over fusion for the endpoint “overall success.”^{93,94} However, “overall success” was not adequately defined. Huppert et al. found at 2 years of follow-up that 2.3% of patients required revision surgery in single level arthroplasty and 3.6% of patients required revision surgery in multilevel arthroplasty.⁹⁵

FUSION RELATED

Adjacent Segment Degeneration

Up to 15% of anterior cervical discectomy and fusion^{96–98} and 9% of all posterior surgery develop adjacent segment disease.⁹⁹ Hilibrand et al. performed a study with follow-up of 21 years and found that in 409 procedures for 374

patients, there was a prevalence of 13.6% of symptomatic adjacent segment disease at 5 years and 25.6% at 10 years.⁹⁶ The risk of developing adjacent segment disease was 3% per patients per year.⁹⁶ Fusionless surgery is theoretically thought to be unlikely to develop adjacent segment disease, although this is debatable.

Pseudarthrosis

The incidence of pseudarthrosis in cervical spine surgery has been reported as 0–50%.^{100–105} Risks of pseudarthrosis include nicotine produces, osteoporosis, number of levels fused, surgical technique, use of antimetabolic agents such as phenytoin, nonsteroidal anti-inflammatory agents (some avoid for at least 10 weeks as they reduce osteoblastic activity), collagen disorders and location of fusion. For patients undergoing anterior cervical discectomy and fusion, pseudarthrosis developed in 33.3% of smokers while in nonsmokers, the rate was 9.6%.¹⁰⁶ Fusion along the posterior para-axial spine and related to degenerative disc disease has higher rate of pseudarthrosis compared to the anterior axial spine.¹⁰⁷

Nonunion rates in odontoid fractures range from 35% to 85%.¹⁰⁸ There is higher risk in elderly with 75% of fibrous nonunion cases found in patients over age of 65.¹⁰⁹ Other factors influencing nonunion especially in Type II odontoid fractures treated with halo immobilization include extent of neurological damage, degree of dens displacement, presence of concomitant C1–C2 fracture, pathological fracture and age of fracture. Radiograph features of pseudarthrosis include extrusion of instrumentation, lucencies across interbody endplate or interbody fusion cage endplate, lucencies around posterior lateral mass screws, instrumentation failure such as broken screws or rods, or gross movement across the fused segment suggests pseudarthrosis. Change of 2 mm in distance between tips of posterior spinous process on flexion and extension lateral radiographs is also suggestive of pseudarthrosis.¹¹⁰

Bone substitutes such as bone morphogenetic proteins (BMP) are commonly used to improve fusion rates. However, there are multiple recent reports of serious complications associated with BMP use including heterotopic ossification forming outside the disc space and into the spinal canal or neuroforamen in 20.8–75% of patients.^{111,112} Vertebral osteolysis has also been described in up to 82% of cases.^{113,114} Other complications include massive airway edema, discharging wound seroma, hematoma formation

Fig. 128.5: Lateral radiograph showing a postlaminectomy kyphosis after C2–C4 laminectomy.

and radiculopathy caused by increased inflammation with use of BMP. Routine use of BMP in the cervical spine is not recommended.

■ DELAYED OR LATE COMPLICATIONS: POSTLAMINECTOMY KYPHOSIS

The incidence of postoperative kyphosis after multilevel cervical spine laminectomy (Fig. 128.5) is 20%.¹¹⁵ Older patients may have partially fused cervical spines and are more stable, thus postoperative kyphosis is more common in younger patients. Laminectomy leads to loss of spinous processes, inter and supraspinous ligaments, laminae and ligamentum flavum, and loss of capsules of facet joints that compromise the posterior stabilizers. With continuing normal flexion forces, kyphosis will result. Kyphosis develops gradually which is why patients are usually well in the early postoperative period. Constant contraction of neck extensor muscles will occur, causing muscle fatigue and neck pain. Progressive kyphosis in children leads to wedging of anterior vertebral bodies due to compression of growing cartilaginous endplates. Sagittal malalignment and axial neck pain are the main issues regarding postlaminectomy kyphosis while neurological deficit is rarely encountered. Laminectomy should be avoided for young patients with lack of preoperative lordosis and disruption of posterior facet joints should be avoided intraoperatively. Fusion should be considered for these patients at the same procedure.

KEY POINTS

- Avoiding prolonged and forceful retractions in anterior surgery can prevent injury to the esophagus, recurrent laryngeal nerve and carotid arteries.
- Prophylactic C5 foraminotomy may help reduce the risk of postlaminoplasty C5 nerve root palsy.
- Careful analysis of the bony and vascular anatomy should be done preoperatively especially when internal fixation is contemplated.
- Additional anterior plating in corpectomy may improve the stability of the construct but failure may occur with graft subsidence.
- Preservation of posterior muscles and their attachments are important for prevention of postoperative neck pain and delayed kyphosis.

Complications of Anterior and Posterior Thoracic Spine Surgery

Atsushi Seichi

Snapshot

» Complications of Anterior Surgery for the Thoracic Spine

» Complications of Posterior Surgery for the Thoracic Spine

INTRODUCTION

Surgery-related complications during thoracic spine surgery, particularly anterior thoracic surgery, carry with them potentially dire outcomes, including death. Evidence-based descriptions on how to prevent complications during thoracic spine surgery are actually difficult to provide. Spine surgeons dealing with thoracic spine surgery should be familiar with the management of intra- and extraspinal canal adverse events, through practice and learning from senior doctors, journals, and textbooks. In the author's country (Japan), decompression surgery for extensive thoracic ossification of the posterior longitudinal ligament (OPLL) or thoracic spinal tumor is representative of a majorly challenging spine surgery (Fig. 129.1). Both posterior and anterior surgeries for thoracic OPLL carry a potential risk of spinal cord injury with or without direct trauma to the spinal cord from the high speed burr, and surgery-related complications are common in the treatment of thoracic OPLL.^{1,2} Information on surgery-related complications in patients with thoracic OPLL can be generalized to any kinds of thoracic spine surgery. This chapter therefore focuses mainly on complications of thoracic OPLL surgery.

COMPLICATIONS OF ANTERIOR SURGERY FOR THE THORACIC SPINE

Wrong Level Surgery

Wrong level surgery is an unavoidable technical error rather than a true complication. In extremely obese

Fig. 129.1: Computed tomography of thoracic ossification of the posterior longitudinal ligament.

patients, confirmation of spinal level from intraoperative radiography using a portable X-ray apparatus is not a completely reliable method for the surgeon to accurately pinpoint the correct level of the anterior thoracic spine. It is not recommended to simply rely on a lateral intraoperative radiograph in the thoracic spine. Reconfirmation using an image-intensifier, with anteroposterior

Fig. 129.2: Snapshot of intraoperative computed tomography after anterior decompression surgery.

views in the operating room, is thus recommended. After finishing decompression procedures, confirmation of the level and evaluation of decompression status by intraoperative CT scan is also helpful (Fig. 129.2).

Vascular Complications

Vascular complications during anterior thoracic surgery are probably under-reported and the true prevalence is unclear. Anterior thoracic surgery carries a potential risk of major complications even in surgery by experienced spine surgeons.³ Direct vascular injuries due to technical errors should be avoided, given the inherent risk of death. Spine surgeons should be very familiar with the vascular anatomy during anterior thoracic approaches, including transthoracic, and sternum-splitting approaches (Fig. 129.3). Care should be taken to prevent contact between vessels and edges of surgical tools, including electrical coagulators. Although experienced spine surgeons seldom encounter an operative shambles, they must have skills to deal with any kind of vascular complication and be able to work closely with reliable chest surgeons and cardiovascular surgeons who can help them.

If a surgeon injures a segmental artery during an anterior approach, the bleeding must be stopped by ligation or coagulation after compressing the bleeding site using a peanut dissector. In patients with chronic vertebral infection, identification and dividing of the segmental vessels is not easy during exposure of the lateral and anterior aspects of the thoracic vertebral bodies.

The aorta is more elastic and less susceptible to injury from retraction than veins. However, intraoperative penetration of a screw placed into a vertebral body can occur and risks creation of a spurious aneurysm and/or fatal

Fig. 129.3: The sternum-splitting approach. Knowledge of the location of the innominate vein (brachiocephalic vein) in the upper chest is critical to avoid injury to this vessel during the sternum-splitting approach.

pulmonary embolism.⁴ When a screw is inserted from the right side of the vertebral body, an overly long screw can penetrate into the aorta on the left side. Precise measurement of the diameter of the vertebral body in which the screw is to be inserted is thus crucial.

The walls of major veins are thin and easily damaged. If an injury to the inferior vena cava or azygos vein occurs, a surgeon has to press strongly on or caudal to the bleeding site with a finger or peanut dissector until a reliable cardiovascular surgeon can assist. The spine surgeon alone trying to effect repairs is likely to only make the situation worse. With a sternum-splitting approach, mobilization, or retraction of the innominate (brachiocephalic) vein without sufficient release of this large vein from the surrounding tissue can lead to its injury. With such injury, the surgeon has to quickly capture the injured site using vessel forceps and make repairs by suturing.

Control of epidural bleeding during anterior thoracic decompression surgery is difficult. To prevent such troublesome bleeding in anterior surgery for thoracic OPLL, the anterior floating technique of thoracic OPLL after thinning the ossified mass using a high-speed diamond burr under microscopy is recommended (Fig. 129.4). Removal of ossified mass may cause excessive bleeding or cerebral spinal fluid (CNS) leakage at the lateral margins of the ossified mass, and this is applicable to anterior surgery for any kind of anterior lesion, including large thoracic disc herniation with calcification. Control of epidural bleeding from a congested Batson's venous plexus

is extremely difficult in patients in the lateral decubitus position, and bipolar coagulation for this bleeding is almost always ineffective. Surgeons must have the skill to manage epidural bleeding by application of hemostatic agents and covering of the agents with surgical sheet (Fig. 129.4).

Spinal Cord Injury

The author prefers microscopic decompression for anterior thoracic spine surgery to prevent spinal cord injury

caused by the high-speed burr. Spinal cord injury may also result from inadequate release of the OPLL (Fig. 129.5A and B). To avoid incomplete decompression due to disorientation to the spinal canal, the author developed anterior navigation surgery for thoracic OPLL.⁵ However, such tools are not available everywhere. Confirmation of complete decompression by intraoperative CT is helpful (see Fig. 129.2).

Injury to the Lung and Pulmonary Complications

Although a chest tube assists lung re-expansion, anterior access to the upper thoracic spine sometimes causes lung atelectasis and pneumonia. Serial chest radiography should be performed after anterior thoracic surgery. Management by a chest surgeon using a bronchoscope is necessary for atelectasis. Tight closure of the chest wall is mandatory to prevent pneumothorax. Gross defect of the chest wall is unavoidable after wide resection of a sarcoma, including chondrosarcoma or osteosarcoma, arising from a thoracic vertebra or rib. If a defect of the chest wall is present, only skin suture following reconstruction of the chest wall by chest patch is acceptable (Fig. 129.6).

The potential risk of inadvertent laceration of the lung during transthoracic approach increases in patients with a past history of chest infection, including tuberculosis.

Fig. 129.4: Anterior floating technique of ossification of the posterior longitudinal ligament at the thoracolumbar junction.

Figs. 129.5A and B: Inadequate removal of thoracic ossification of the posterior longitudinal ligament. (A) Preoperative computed tomography (CT) myelography. (B) Postoperative CT.

Fig. 129.6: Reconstruction of the chest wall by chest patch.

For such patients, an extrapleural approach is recommended. For lung injury, direct repair by suturing and covering the injured site with fibrin glue is necessary.

Prevention and Management of Incidental Durotomy

Management of CNS leakage is addressed in another chapter. However, the management of CNS leakage after anterior thoracic surgery has a special aspect, in that leakage spreads into the pleural cavity. In anterior surgery for thoracic OPLL, a consistent method for decreasing the risk of CNS leakage is to avoid complete anterior removal of the OPLL. A direct repair of anterior dural defect after removal of the ossified mass combined with dural ossification is almost impossible. To prevent CNS leakage in anterior surgery for thoracic OPLL, the anterior floating technique of thoracic OPLL after thinning the ossified mass by a diamond burr under microscopy is recommended (see Fig. 129.4). Again, surgeons should remember that removal of the ossified mass may cause excessive bleeding from Batson's venous plexus and/or CNS leakage at the lateral margins of the ossified mass. Placement of fibrin glue is usually ineffective for anterior CNS leakage. If drainage by a chest tube without suction pressure does not fall to <100 mL a day, a drainage system without suction pressure should remain in place. If drainage does not decrease day by day, additional lumbar drainage is an option. The author has experienced cases requiring placement of a chest tube for up to 4 weeks, with no need for surgical repair due to a failure of conservative treatment.

Pleural Cavity Infection

After anterior thoracic surgery, fluid in the chest drain is bloody and/or serous in the normal course of events. Cloudy products, high fever, and elevations in the white blood cell (WBC) count and C-reactive protein (CRP) level indicate pleural cavity infection. Endoscopic debridement and daily irrigation using a double chest tube with intravenous administration of sensitive antibiotics are recommended until the total daily volume of drainage decreases to 100 mL or less and WBC and CRP levels normalize. Before removal of the chest tube, negative results need to be obtained from repeated cultures of drain effluent. When intrapleural infection cannot be conservatively controlled, the worst scenario is wide-open drainage of the chest cavity and open irrigation until good granulation is formed in the chest cavity before delayed closure.

Chylothorax

The thoracic duct lies on the right side of the aorta within the posterior mediastinum. Unrecognized thoracic duct injury can occur during anterior thoracic spine surgery for large spinal tumors arising from the upper thoracic spine, including giant cell tumor, chondrosarcoma, and osteosarcoma. Diagnosis of thoracic duct injury is almost always delayed. Chyle has a variably milky appearance, attributable to its fat content. Watery, creamy fluid in the drainage system suggests thoracic duct injury. Oral feeding should be discontinued and intravenous fluids should be administered along with total parenteral nutrition (TPN) until the leakage of chyle into the drain is almost zero.

COMPLICATIONS OF POSTERIOR SURGERY FOR THE THORACIC SPINE

Spinal Cord Injury

The thoracic spine is naturally kyphotic and decompression laminectomy is theoretically less effective than in the cervical spine. However, anterior removal of the thoracic OPLL in front of the severely compressed and already debilitated spinal cord is extremely dangerous because of the risk of postoperative paraplegia. Posterior decompression with instrumentation has been considered the safest procedure for thoracic OPLL.⁶ However, subtle spinal movement immediately after laminectomy can cause intraoperative spinal cord injury in posterior surgery for thoracic OPLL.⁷

To prevent this complication, temporary instrumentation should be performed before starting decompression procedures.^{6,7} Thoracic ossification of the ligamentum flavum (OLF) frequently coexists with thoracic OPLL. Inadequate decompression also leads to neurological deficit. Preoperative planning by CT and MRI is important to fully complete posterior decompression. Intraoperative navigation and intraoperative ultrasonographic evaluation are useful to confirm achievement of sufficient decompression.⁸

Vascular Complications and Postoperative Epidural Hematoma

Posterior thoracic surgery except for the costotransversectomy approach endangers no major vessels. However, inadequate hemostasis, particularly for small arteries accompanying thoracic spinal roots, can lead to the formation of an epidural hematoma. Epidural hematoma is an avoidable complication of posterior thoracic spine surgery and the risk increases with multilevel extensive laminectomy for thoracic OPLL. Postoperative worsening of paralysis requires emergent exposure for open drainage and hemostasis without MRI investigation. Surgeons should be reminded that repeated hematoma may occur after the first emergent surgery. Delayed epidural hematoma can also occur up to 1 week after posterior decompression surgery for thoracic OPLL in the author's experience. The author recommends placement of suction drainage for around 1 week and prohibition of supine position to decrease pressure on the wound and epidural space.

Total en bloc spondylectomy for malignant spinal tumor only through a posterior approach poses a risk of avulsion injury of a segmental artery from the aorta.⁹ Management of this complication has not been reported in the past and the author has no direct experience of this event, but is aware of cases in which it arose. According to personal communications, an anterior approach after changing the position of the patient while the surgeon pushes on the bleeding site with a finger and assistance from a "superior" cardiovascular surgeon is necessary to manage this trouble.

Intraoperative bleeding due to perforation of the aorta or a segmental artery by a pedicle screw can also be associated with significant morbidity. Placement of intra-aortic stent grafts through the femoral artery after packing the posterior wound is one option for this type of arterial injury.¹⁰

Fig. 129.7: Large spinal pseudomeningocele created by dural tear during previous posterior surgery for ossification of the posterior longitudinal ligament. Surgical closure of a CSF fistula combined with lumbar drainage is required for such a large pseudomeningocele.

Management of Incidental or Intentional Durotomy

Dural ossification is common in patients with OPLL, OLF, or both.¹¹ Ossification of the ligamentum flavum can be posteriorly removed while reserving the arachnoid membrane under microscopic surgery. Resection of the intradural meningioma can be accomplished while reserving the arachnoid membrane.¹² Even with those techniques, CSF leakage can occur. Complete repair of a dural defect after removal of a dumbbell-shaped spinal cord tumor is almost impossible. Thus, even after watertight dural closure, CSF leakage can remain. Placement of fibrin glue is usually ineffective for posterior CSF fistula after posterior thoracic spine surgery. If the drainage does not reduce to <50 mL a day, placement of a drainage system without suction pressure should be retained for >1 week, by which time wound healing of the muscle layer can be expected. Prevention of subcutaneous fistula formation (Fig. 129.7) is a goal of this method. Lumbar drainage remains an option.

Complications of Pedicle Screw Use

Surgeons should be extremely careful during final tightening of pedicle screws not to injure the uncovered spinal cord after laminectomy by mishandling the screw holder. Screw misplacement is the most common complication encountered with thoracic pedicle screw placement. Medial perforation can cause spinal cord injury (Fig. 129.8). Lateral per-

Fig. 129.8: Thoracic pedicle screws placed through the spinal canal. The patient with thoracic ossification of the posterior longitudinal ligament woke up with worsening paraparesis, which was exacerbated following repeat surgery for screw removal.

foration and/or overpenetration by excessive screw length can cause injuries of the aorta or segmental vessels on the anterior surface of the vertebra. Massive bleeding from the aorta or segmental artery is very rare, but if rapidly progressive hypotension occurs during or after surgery, surgeons have to remember this complication and have the ability to call cardiovascular surgeons in to achieve the necessary anterior exploration to cut the perforated screw and repair the injured vessel.^{10,13} An asymptomatic screw in direct proximity to the aorta should be replaced because of the risk of future complications.¹³ Intraoperative detection of a medially perforated screw by portable X-ray is sometimes difficult. Intraoperative CT is useful to allow early revision of a misplaced screw.^{14,15} Although a navigation system is useful, surgical experience and mastery of the technique are crucial to avoid the misplacement of screws.

KEY POINTS

- Spine surgeons should be familiar with the vascular anatomy during anterior thoracic approaches, including transthoracic and sternum-splitting approaches.
- When a major vascular injury occurs, quick consultation with a cardiovascular surgeon is mandatory.
- Spine surgeons should have a detailed knowledge regarding the management of pulmonary complications, including chylothorax.
- Incidental CSF leakage can be managed conservatively.
- Wrong level surgery can be avoided by anticipating difficulties in identifying and radiographically confirming the correct segments.

- Intraoperative fluoroscopy and intraoperative or postoperative CT is helpful to confirm accurate screw placement and decompression.

Snapshot

» Anterior Approach

» Posterior Approach

INTRODUCTION

Over the years, the evolution in the treatment of spinal disorders was motivated by enhancing patient outcome by minimizing procedure-related pain and complications, facilitating a quicker return to daily activities, and reducing overall health-care costs. The foundation of many tissue sparing techniques was initially developed to address lumbar-related pathologies and symptoms, and these techniques were adapted and modified for applications in other areas of the spine, including the cervical spine.

One of the earliest publications on cervical spondylosis resulting in posterior cervical disc herniation and spinal cord compression was reported by Bailey and Casamajor¹ in 1911. Mixter and Barr² supported a posterior laminectomy to surgically remove cervical and lumbar disc herniations in 1934, grouping both cervical and lumbar disc herniations together. This approach became the standard of care for the operative management of lumbar and cervical disc herniations for the next decade. In 1943, Semmes and Murphey³ described cervical disc disease associated with radiculopathy as a distinct entity. In time, the consequences associated with cervical laminectomy (postoperative kyphosis, excessive bone and tissue removal, and risk of spinal cord injury) became a significant concern. In the 1950s, both Robinson and Smith⁴ and Cloward⁵ developed the anterior cervical discectomy and fusion in an effort to surgically treat cervical disc disease and spondylosis compromising neural integrity, and to avoid the intraoperative

and postoperative complications associated with laminectomy alone. The anterior approach with discectomy and reconstruction has subsequently been accepted as the utilitarian approach in the treatment of both myelopathy and radiculopathy. Although very safe and very well tolerated by the patient, the anterior dissection is not without pitfalls. To minimize the complications (dysphagia, dysphonia, vertebral artery injury) of an anterior approach, a posterolateral laminoforaminotomy was promoted by Frykholm⁶ in the 1950s and by Scoville and Whitcomb⁷ in the 1960s in the treatment of cervical nerve root impingement. Even further, in an effort to avoid destabilization with a posterior laminoforaminotomy and avoid an anterior discectomy and fusion, an anterior cervical foraminotomy was developed and reported by Verbiest⁸ in 1968. Multiple authors have described variations in this procedure over the next 30 years, including Hakuba,⁹ Lesoin,¹⁰ and Snyder and Bernhardt.¹¹

Over the past 10 years, microendoscopic cervical procedures with a muscle-splitting/sparing approach using tubular retractors and a videoendoscope or operating microscope have been used with good results. These procedures are based on the successful experience and development afforded by prior experience in lumbar spine applications. Endoscopic procedures minimize excessive tissue injury or bone removal, avoid potential destabilization of the spine, decrease postoperative discomfort, allow a quicker return to activities, and minimize hospital stays when addressing cervical spine pathologies (Fig. 130.1). These

endoscopic procedures can be used for the treatment of foraminal stenosis or a herniated disc in the cervical spine. Roh¹² described an endoscopic foraminotomy performed in cadavers in 2000 using the MED system (Medtronic Sofamor Danek, Memphis, TN, USA). Clinical outcomes using this approach have been promising, attaining a high success rate reported by Adamson,¹³ Burke,¹⁴ Fessler,¹⁵ and Yuguchi.¹⁶ Similar minimally invasive techniques have been used to address cervical pathologies from an anterior approach, as described by Chiu¹⁷ and Fontanella.¹⁸ Furthermore, a cervical microendoscopic decompression for spinal stenosis was developed and reported in 2005 by Perez-Cruet¹⁹ to decrease the morbidity associated with extensive laminectomy or laminoplasty. Such a procedure remains technically challenging due to the constraints of the degenerative spinal canal. Further trials are underway to determine its efficacy versus traditional approaches. Microendoscopic techniques have also been reported for the treatment of odontoid fractures,²⁰ decompression of basilar invagination, high cervical clivus abnormalities, pseudogout granulation mass, and Chiari malformations.²¹ These approaches decrease the opening and resection of the skull base, reducing postoperative complications and speeding recovery.

■ ANTERIOR APPROACH

Minimally Invasive Anterior Cervical Foraminotomy

Minimally invasive anterior approaches are useful techniques in the treatment of cervical radiculopathy through a

transuncal approach.^{22,23} In cases of cervical radiculopathy, a decompression can be done without fusion, preserving the intervertebral disc and completely decompressing the exiting nerve root. Anterior approaches provide direct access to ventral lesions and have the potential for decreased operative time, shortened hospital stay, and no need for implants or immobilization. The indications for minimally invasive anterior cervical foraminotomy are restricted to cervical radiculopathy, but can include bilateral and multilevel foraminal stenosis. Contraindications to this approach are severe central stenosis resulting in cervical myelopathy, aberrant vertebral artery anatomy, ossification of the posterior longitudinal ligament (OPLL), and severe spondylosis. Minimally invasive techniques must also be used with caution in cervical trauma.

Surgical planning²⁴ focuses on an extensive evaluation of the lateral one-third of the motion segment. Preoperative diagnostic imaging should consist of anteroposterior, lateral, oblique, and flexion–extension radiographs of the cervical spine. Advanced imaging such as magnetic resonance imaging (MRI) and computed tomography (CT) scans are useful for delineating the neural/soft tissue and bony anatomy, respectively. There are four key elements to take into consideration when planning an anterior minimally invasive approach. These are the longus colli, uncinat process, vertebral artery, and exiting nerve root. Positioning for surgery is similar to that of a routine anterior discectomy and fusion, with patients in the supine position on a radiolucent table. Excessive extension is avoided during patient positioning. Gardner-Wells traction is not necessary, but traction on the shoulders may be necessary to visualize caudal cervical levels. Intraoperative fluoroscopy is used to mark the initial skin incision, and this is made in a skin crease when possible. A standard Smith-Robinson approach is used to expose the pathologic side causing radiculopathy. The lateral third of the vertebral column is identified with the elevation of the longus colli muscle using a Penfield-1 and a microbipolar. Retractors are placed in the usual manner, deep to the longus colli muscles. The medial and lateral margins of the uncinat process are identified and exposed using Kittner dissection and a Penfield-4. Full exposure is achieved when the uncinat process and lateral thirds of the cranial and caudal vertebral bodies and disc are visualized. It is recommended to perform the remainder of the procedure with an intraoperative microscope, as loupe magnification may not provide sufficient magnification or illumination. A Penfield-4 is used to expose the lateral border of the uncinat process of the caudal vertebral body along a plane

between the vertebral artery and the uncinat process. The concave side of the Penfield-4 should be placed along the uncinat process's lateral margin, protecting the vertebral artery from iatrogenic injury. The uncinat process is then resected using a long-handled high-speed drill using a 2.2/2.3 mm matchstick burr (Midas Rex Legend, Fort Worth, Texas/Anspach, Palm Beach Gardens, FL, USA). Five to six millimeters of bone is drilled away, maintaining a 1–2 mm thick margin of bone between the drill and Penfield-4. Frequent saline irrigation is encouraged along with use of bone wax for bleeding cancellous bone. Drilling is continued in a cephalad direction toward the nerve root posteriorly, along with fluoroscopic guidance to identify trajectory and depth. Drilling straight posteriorly will lead to the superior pedicle margin and away from the neuroforamen. The posterior longitudinal ligament (PLL) is identified, and a plane is developed between the PLL and the posterior aspect of the vertebral body. Cervical Kerrison rongeurs (Aesculap, Tuttlingen, Germany), 1.0-, 1.5-, or 2.0-mm, are used to remove remaining bony elements, osteophytes, cartilage, periosteum, and PLL. The lateral margin of the uncinat process is removed by a Penfield-4 by using a lateral to medial “sweep” to fracture remaining bone from the vertebral body. Some authors prefer to leave this shelf of bone to protect the vertebral artery.²⁵ However, when doing this, care must be taken to determine that the remaining bone will not cause persistent compression of the exiting nerve root. Meticulous hemostasis is critical, using a combination of bipolar cautery, gelfoam powder, and Floseal (Baxter Health Care Corporation, Deerfield, IL, USA) or Surgifoam (US surgical). The path of the nerve root is visualized and decompressed medially from its origin from the spinal cord and laterally to the area posterior to the vertebral artery. A blunt microneur hook can be passed along the course of the nerve to ensure all disc fragments have been removed and an adequate decompression has been performed. A drain may or may not be used.

Minimally Invasive Anterior Cervical Corpectomy

A minimally invasive anterior approach can also be used for central corpectomy to treat OPLL.²⁶ Traditional anterior approaches for corpectomies afford a direct approach to decompression of the spinal canal.²⁷ However, it can also result in postoperative kyphotic changes,^{28,29} increased blood loss, and potential for implant related complications. Hirano et al. has described a minimally invasive

central corpectomy (MICC) for the treatment of cervical segmental ossified PLL, which includes reconstruction with a cylindrical titanium cage containing autologous local bone graft. The indications for MICC are limited to OPLL within two disc levels. Corpectomy should not be more than half of the vertebral body height to avoid early vertebral settling and progressive kyphosis due to graft settling. Contraindications include severe osteoporosis, patients on hemodialysis, and smokers. The characteristics of the OPLL and dural ossification are extremely important when considering MICC.³⁰ The OPLL with extensive lateral extension is inaccessible via the MICC window, and OPLL adherent to the dura poses a significant risk for CSF leak. If the above criteria are not met, a traditional corpectomy or a posterior-based approach should be the treatment of choice to avoid significant complications. In cases where the OPLL is adherent to the underlying dura, “floating” the ossified portion is an acceptable option. Minimally invasive central corpectomy should be an option only in cases with segmental, small continuous or mixed type of OPLL, and without adhesion of the OPLL with the adjacent dura.

The procedure includes upper- or lower-half central corpectomy of the involved cervical vertebral body, transdiscal decompression of the adjacent disc level, dissection and removal of the OPLL behind the vertebral body, and instrumentation/fusion with a cylindrical titanium cage. As described by Hirano et al., anterior plate fixation is not necessary. Care must be taken to preserve the bony end plates to avoid early subsidence of the cage. Postoperatively, patients are immobilized with a soft cervical collar for 1 week, and patients are followed at routine intervals.

POSTERIOR APPROACH

Minimally Invasive Posterior Cervical Foraminotomy

Posterior approaches to the cervical spine are an essential tool for a spine surgeon for the treatment of various pathologies. Posterior cervical laminoforaminotomy continues to be an effective option to treat radiculopathy caused by foraminal stenosis or lateral herniated discs, with success rates ranging from 92% to 97%.^{31,32} In patients with cervical spondylotic myelopathy, reported rates of neurologic improvement vary from 63% to 83%^{33–36} with a posterior decompression either in laminectomy or laminoplasty. Posterior-based procedures also do not carry the risk of recurrent laryngeal nerve paralysis, esophageal injury, dysphagia, dysphonia, vascular injury, and adjacent segment

disease.^{37,38} Traditional open posterior approaches require extensive soft-tissue stripping of the paraspinal musculature, which can lead to significant pain, disability, and weakness with neck extension (especially if the extensor attachments at C2 and C7 are disrupted). Posterior approaches without fusion also have a limited role in patients with cervical kyphosis. The fundamental idea behind tissue-sparing techniques in the cervical spine is to minimize approach-related soft-tissue injury, pain, and dysfunction. With the development of sequential dilation of muscle fibers and tubular retractor systems with specialized instrumentation and improved endoscopic equipment, minimally invasive procedures can be used safely for posterior cervical decompressions.

A cervical microendoscopic laminoforaminotomy was first described in a cadaver model to demonstrate its feasibility. The procedure was a direct evolution from the application of tubular retractor systems in the lumbar spine for discectomy and decompression. The technique was shown to have equivalent nerve root decompression and bony resection as traditional open approaches (Burke,¹² and Roh¹⁴). In clinical application, the microendoscopic procedures have reported similar success rates as compared to their open counterparts.³⁹ As expected, the less invasive approach has less blood loss, postoperative pain, and shorter hospital stays as compared to the open procedure. Gala et al.⁴⁰ reviewed clinical outcomes in patients undergoing a cervical microendoscopic foraminotomy/discectomy and found statically significant improvements in mean visual analog scale scores for headache, neck pain, and arm pain compared to their preoperative levels. Mean neck disability index scores also showed a significant improvement, as short form 36 scores also showed improvement in the bodily pain, physical function, and role limitations due to physical problems subscales. There is a theoretical decreased risk of developing iatrogenic kyphosis due to preservation of the native osteoligamentous anatomy of the cervical spine especially the posterior ligamentous complex. The indications for a cervical microendoscopic laminoforaminotomy include one and two level unilateral foraminal stenosis, residual radicular symptoms after anterior cervical discectomy and fusion, and radiculopathy caused by cervical disc disease, where an anterior approach is contraindicated (previous radiation, tracheostomy, etc.). Contraindications include gross instability, significant ventral compression (OPLL), severe central stenosis or central disc herniation, cervical myelopathy, kyphotic deformity, and axial neck pain without radicular

Fig. 130.2: Patient positioning in the sitting position for posterior endoscopic foraminotomy. Fluoroscope is placed to provide a lateral view of the cervical spine. Video monitor is placed over the arm of the fluoroscopic unit.

symptoms. Proper preoperative evaluation consists of a thorough history and physical, as well as MRI (or CT myelogram if unable to obtain MRI) and cervical spine X-rays (anteroposterior, lateral, and flexion-extension views). Electromyography (EMG) may be useful to distinguish a peripheral nerve entrapment from a cervical radiculopathy. Diagnostic selective nerve root blocks, if effective, increase the potential for a good outcome after decompression. The equipment needed for this procedure is a Mayfield (Integra LifeSciences, Plainsboro, NJ, USA) device compatible with a semisitting position, a tubular retractor system with an endoscope, an endoscopic monitor with camera, cervical Kerrison rongeurs (1.5 and 2 mm), microcervical bayonnetted curettes, a high speed drill, and intraoperative fluoroscopy.

The procedure can be done in the sitting or the prone position (Fig. 130.2). The sitting position offers several advantages including less bleeding at the site of decompression and better radiographic imaging of the cervical spine allowing for more accurate placement of the tubular retractors while minimizing the skin incision. Neuro-monitoring (somatosensory-evoked potentials, EMG, or transcranial motors), arterial lines, and Foley catheters are not routinely used. Neuro-monitoring may be used in cases of severe cervical stenosis which is a relative contraindication to performing a foraminotomy alone. Precordial Doppler may be useful to detect air embolism, although with a small exposure this risk is low. The relative incidence of asymptomatic air embolus is thought to be 1:2,000. The semisitting position affords decreased blood pooling in

Fig. 130.3: The lateral fluoroscopic view of the cervical spine with the first dilator docked at the facet joint of C7-T1 that can be easily imaged with the patient in the sitting position.

the operative field, reduced blood loss, shorter operative times, and provides improved lateral fluoroscopic images because of the gravity-dependent position of the shoulders. The neck is slightly flexed, and the Mayfield clamp is attached to the table mounted cross-bar. The C-arm is brought in and adjusted to obtain a perfect lateral image of the cervical spine. The fluoroscopy screen is placed usually to the right of the surgeon, and the endoscopic monitor is placed in front of the surgeon. The operative levels are reconfirmed with intraoperative fluoroscopy, and a skin incision is marked, approximately 16–18 mm in length 5–10 mm from midline toward the symptomatic side. In cases where more than two levels are symptomatic, a staged decompression is a better approach to decrease operative times and allows the patient to still go home the same day. A straight Kelly clamp is used to spread down to the lamina-lateral mass junction. Use of guidewire is contraindicated in the cervical spine as inadvertent penetration into the spinal canal can occur with disastrous consequences. Even with the Kelly clamp, care must be taken to avoid entering the interlaminar space. The initial dilator is then docked at the lamina-lateral mass junction at the lateral edge of intralaminar space (Fig. 130.3). Sequential dilation is performed until a 16 or 18 mm tubular retractor is in place. The position of each dilator is confirmed with lateral fluoroscopy. Once the tubular retractor is in place, it is attached to the table mounted flexible arm, and the dilators are removed. A 25° endoscope is inserted into the tube to visualize the bottom of the field (Fig. 130.4). Pituitary rongeurs are used to remove any muscle in the

Fig. 130.4: A 16-mm tubular retractor is docked on the lamina–facet junction of the targeted level and secured to a mechanical arm. A 2.5-mm glass endoscope attached to a three-chip video camera using a custom C-mount allows visualization of the anatomic structures in high magnification.

operative field, and straight and angled bipolar forceps are used for hemostasis. A microcervical curette is used to further delineate the anatomy of the inferior edge of the rostral vertebrae and the corresponding lateral mass (Fig. 130.5). A high-speed matchstick burr is then used to start the laminoforaminotomy by removing the inferolateral edge of the lamina of the rostral vertebrae, followed by the medial edge of the lateral mass. This exposes the superomedial one-third of the superior facet of the caudal vertebra that is further thinned down with the burr (Fig. 130.6). Care must be taken to preserve at least 50% of the facet joint to avoid instability.⁴¹ The ligamentum flavum is then removed to expose the lateral edge of the dura and proximal portion of the nerve root. A 1.5 or 2 mm Kerrison rongeur can then be used to complete the laminoforaminotomy safely, decompressing from the medial border of the caudal pedicle to the lateral border of the caudal pedicle (Fig. 130.7). Dural pulsations can be seen in the nerve root sleeve after sufficient decompression. A 2-0 angled curette can then be used to decompress the exit zone of the foramen. A methylprednisolone-soaked piece of Gelfoam may be placed over the nerve root to reduce postoperative inflammation (Figs. 130.8 and 130.9). Early mobilization is encouraged, and no cervical immobilization is necessary. Generally, patients can be discharged to home after 2–3 hours if medically stable (Fig. 130.10). Postoperative medications include a narcotic analgesic with acetaminophen and a muscle relaxant.

Fig. 130.8: The intraoperative view of the muscular split as the tubular retractor is slowly withdrawn.

Fig. 130.9: The postoperative axial CT image after right C7-T1 foraminotomy.

Fig. 130.10: Healed incision after endoscopic laminoforaminotomy.

Fig. 130.11: The tube is initially angled toward the lateral mass to perform the foraminotomy.

Fig. 130.12: After the foraminotomy is completed, the tube is then angled medially to allow resection of the ipsilateral lamina and the undersurface of the contralateral lamina.

Complications of the cervical endoscopic approaches include infection, CSF leak, air embolism and neurologic complications. The risk of infection and CSF leak are most common, ranging from 1%¹³ to 8%.¹⁵ Because the operative field is narrow, small inadvertent durotomies can be treated by simply covering the defect with muscle, fat, Gelfoam, dural substitute followed by fibrin glue or synthetic sealants followed by bed rest for 24 hours. For larger tears, a lumbar CSF drain may be necessary for 2–3 days. Post-operative pseudomeningoceles and CSF-cutaneous fistulas are rare due to the lack of dead space and small incision.

Venous air embolism may occur during any operative procedure in which the operative site is above the level of

the heart. Venous air embolism of some degree is detected in all patients undergoing neurosurgical procedures such as craniotomy in the sitting position.⁴² This sets up a condition of negative venous pressure relative to the atmosphere, which favors the passage of air into the circulation. However, these procedures tend to expose a large surface of exposed bone and dura to air in contrast to the minimal bony exposure in endoscopic cases. Gala et al.⁴⁰ have no reported cases of venous air embolism. Potential neurologic complications include nerve root injury from decompression or manipulation and direct spinal cord compression during docking, dilation or decompression.

Microendoscopic Cervical Decompression for Spinal Stenosis

Gala et al.⁴⁰ also describe a cervical microendoscopic decompression of stenosis. After the ipsilateral laminotomy is completed, the ligamentum flavum is left in place to protect the dura (Fig. 130.11). The endoscopic tube is angled toward the contralateral side, and a subligamentous plane is dissected along the undersurface of the spinous process. A high-speed burr with a guard sleeve extended is then used to progressively remove the bony undersurface of the spinous process and contralateral lamina across to the contralateral facet (Fig. 130.12). This avoids any downward pressure on the dura and spinal cord. The ligamentum flavum may now be removed with curettes and Kerrison rongeurs. Once there is adequate decompression, the tube is directed to its original position to remove the ipsilateral ligament and bone, which will reveal a completely decompressed thecal sac (Fig. 130.13).

Fig. 130.13: The view of decompressed spinal canal and dural sleeve after microsurgical laminoplasty.

Fig. 130.14: The tube is placed 20° cephalad to dock onto the lateral mass to allow appropriate angulation for instrumentation.

Minimally Invasive Posterior Lateral Mass Instrumentation and Fusion

Mikhael et al.⁴³ describe posterior instrumented fusion using lateral mass screw placement and bilateral foraminotomy through an endoscopic tubular approach. The indications for minimally invasive lateral mass screw placement for posterior cervical arthrodesis are instability from C3 to C7, fusion for prior posterior cervical laminectomies, or in conjunction with anterior corpectomy and fusion using strut grafting. Lateral mass screw placement is contraindicated in patients with lateral mass hypoplasia, lateral mass fracture or aberrant vertebral artery anatomy, making lateral mass screw placement difficult or impossible. The procedure is performed through a midline vertical incision in line with the spinous processes. This incision is usually 3–4 cm long to accommodate the tubular retractors. The incision is centered over the pathologic level for single-level procedures, and should be centered one level above the most inferior surgical level when performing multilevel procedures. The underlying fascial incision is also 3–4 cm in length and is made 4–6 mm off of midline toward the pathologic side. If a bilateral arthrodesis is being performed, two separate fascial incisions are made. Soft tissues are bluntly dissected until the lateral mass and facet joint of interest can be palpated. A dilator is then placed over the facet joint in a trajectory 15–20° cephalad to stay in-line with the path for screw placement, and the level is confirmed with intraoperative fluoroscopy. Serial dilation is used in the same manner as described previously, maintaining the identical trajectory, and the tubular retractor is placed (Fig. 130.14). The lateral mass and

facet capsule can now be fully exposed. A skirted retractor can be used for deeper retraction over multiple levels. It is critical to maintain the 15–20° of cephalad angulation with complete visualization of the medial and lateral borders of the lateral mass for proper instrumentation. Caution must be exercised during exposure to avoid violating the facet capsules that are not to be fused. The starting point for the lateral mass screw is in the middle of the lateral mass in the cranial-caudal plane and 1 mm medial to the midline in the medial-lateral plane. This starting point can be marked by creating an indentation in the cortex using the 2 mm matchstick burr. A 2.5 mm drill 14 mm in length is then placed at the starting point and oriented approximately 15–20° cephalad and 30° in a medial to lateral direction, parallel to the slope of the facet joint (Fig. 130.15). This orientation avoids drilling into the facet joint, avoids the nerve root inferiorly, and avoids the vertebral artery, typically in the midline of the lateral mass. A ball-tipped probe is then inserted into the hole to palpate for a breach, followed by a tap, probe, and 3.5 mm screw. These steps are repeated at subsequent levels. Intraoperative fluoroscopy is then used to confirm proper placement of instrumentation. The rod can then be engaged to the screws with a pivoting inserter. Complications with this approach arise when there is inadequate visualization of the lateral mass. If the proper trajectory cannot be determined, or if the anatomic landmarks are obscured, conversion to an open approach may be necessary. Complications associated with improper screw placement are vertebral artery injury, nerve root injury, poor fixation, and violation of the facet joint leading to postoperative pain.

Fig. 130.15: The trajectory of the lateral mass bone screw is 15–20° cephalad and 30° of lateral angulation.

Minimally Invasive Cervical Laminectomy and Laminoplasty

The clinical application of minimally invasive multilevel decompressions (laminectomy and laminoplasty) has not been well-studied. Significant technical challenges exist when performing minimally invasive laminoplasty, including difficulty with elevation of the lamina and insertion of bone grafts. Perez-Cruet¹⁹ and Wang³⁶ examined the feasibility of minimally invasive multilevel laminoplasty and laminectomy in cadaver models, showing it is possible to expand the cross-sectional area of the spinal canal by 43%. Minimally invasive approaches in general must provide at least equivalent patient outcomes when compared with traditional open procedures. As techniques improve, the ability to treat increasingly complex problems of the cervical spine *via* minimally invasive means will most likely continue to grow.

Management of Inadvertent Durotomies

Inadvertent durotomy is one of the most common complications in spine surgery. Unrecognized or improper treatment of durotomies can lead to postural headaches, back pain, nausea, and more serious consequences such as pseudomeningocele formation, cutaneous CSF fistula,⁴⁴ intracranial hemorrhage, meningitis, and neurologic deficit. The rates of pseudomeningocele formation and cutaneous CSF fistulas/persistent CSF leaks are believed to be lower in minimally invasive approaches due to the decreased dead space from smaller incisions and muscle-splitting approaches.⁴⁵

Ruban and O'Toole⁴⁶ developed a treatment algorithm for the treatment of inadvertent durotomies in minimally invasive spine surgery. All patients with partial thickness durotomies and intact arachnoid were treated with fibrin glue only. For full-thickness durotomies, a primary repair was attempted. Dorsal or dorsolateral durotomies were typically repaired primarily using interrupted 4-0 Nurulon (Ethicon) sutures. If the repair was not watertight to a Valsalva maneuver, a small piece of locally harvested paraspinous muscle was sutured to cover the defect. Fibrin glue was then applied over the repair, whether it was watertight or not. Durotomies located at the lateral edge or undersurface of the bony window, or on the ventral surface of the dura, are virtually impossible to repair. For these cases, a small blood-soaked piece of Gelfoam was laid over the dural defect, followed by application of fibrin glue. Once the fibrin glue was allowed to congeal, the minimal access retractor was slowly removed, and meticulous hemostasis was obtained by bipolar cauterization. The fascia was then closed with 0-Vicryl sutures in an interrupted fashion, followed by 2-0 Vicryl for the subcutaneous layer, followed by Dermabond (Ethicon). No drains were used. The patients were kept on strict bed rest overnight and were allowed to fully mobilize the next morning. No additional antibiotics were administered. In this case series, no patient developed a postoperative cutaneous CSF fistula or pseudomeningocele. No patient complained of persistent headaches or nausea, and there were no new neurological deficits attributable to durotomy after surgery. Of note, a commercially available, specialized set of dural repair instruments was used that includes two modified needle drivers and a bayoneted Chitwood Knot Pusher (Scanlan International, St. Paul Minnesota).

Minimally invasive procedures are usually performed through tubular retractors, making dural repair difficult. These small tubes limit the use of traditional instruments used for dural repair, especially for opening and closing the instruments as well as achieving the proper angulation. Chou et al.⁴⁷ described a technique to circumvent this difficulty using commonly available instruments in the operative room for primary dural closure. Using a standard micropituitary rongeur, 5-0 Prolene suture (Ethicon Inc, Somerville, NJ, USA), and a laparoscopic knot pusher, primary dural repair can be performed.

The U-Clip (Medtronic, Minneapolis, MN, USA) can also be used to assist in primary closure of durotomies in minimally invasive spine surgery. Song and Park⁴⁸ described a technique to close durotomies and examined the performance of the U-Clip for the closure of inadvertent durotomy occurring during minimally invasive spine

surgery. The U-clip is a novel device that can achieve tight tissue approximation without the need for knot-tying and excessive suture manipulation, making it an ideal tool to use in minimal access surgery. The U-Clip is a self-closing nitinol clip attached to a conventional surgical needle by a flexible suture-like member. It was initially designed for coronary artery anastomoses, as it allows for tight tissue reapproximation without the need for knot-tying and excessive suture manipulation.⁴⁹ When a durotomy occurred, the edges of the dura were identified, reapproximated, and repaired primarily using one or more U-clips in an interrupted fashion. The U-clip is then positioned across the dural edges appropriately, and a bayoneted needle driver is used to compress the “release sleeve” that attaches the U-Clip to the flexible member, deploying the clip. After detachment, the U-Clip reshapes itself from a U-shape into a closed loop. When more than one U-Clip was needed to close the durotomy, the U-clips were placed at 2 mm intervals in an interrupted fashion. All patients were mobilized immediately, and out of seven patients, six were discharged as outpatients. No patients in this study had clinical symptoms of a CSF leak at follow-up, and all incisions healed without evidence of wound infection or pseudomeningocele.

Minimally Invasive Tumor Resection

Spinal tumors are relatively rare lesions, occurring with an incidence of 1–2/100,000.⁵⁰ Two-thirds are extramedullary, either intra- or extradural.⁵¹ Schwannomas, neurofibromas, and peripheral nerve sheath tumors make up 40% of extramedullary lesions, meningiomas an additional 40% and filum ependymomas 15%.⁵² Intramedullary lesions can be of glial origin (ependymomas and astrocytomas), and hemangioblastomas, metastases, other glial tumors, and benign lesions are also seen.⁵³ The clinical presentation of spinal tumors is consistent with a slow growing mass. Patients may initially present with neck pain, radiculopathy, and myelopathy depending on tumor size and location. The diagnosis is usually confirmed by MRI. The treatment for all extramedullary tumors is complete surgical excision. For intramedullary tumors, gross total excision is attempted without causing iatrogenic neurologic compromise. The traditional procedure requires a midline incision, muscle stripping, and multilevel laminectomy to provide access to the tumor. Minimally invasive techniques aim to limit the extent of tissue destruction/dissection, while achieving the same surgical goal, avoiding the incidence of iatrogenic instability. These minimally invasive approaches may reduce postoperative pain, reduce blood

loss, speed recovery, shorten hospital stay, and maintain spinal structural integrity.

Haji et al.⁵⁴ describe a surgical technique for the resection of intramedullary, intradural extramedullary, and extradural spinal neoplasms using a tubular retractor. In their series, only two patients had cervical tumors. One was a 54-year-old male with a C6 intradural atypical meningioma (WHO Grade II) and a 72-year-old female with a C5–C6 intradural meningioma. The patient with the C6 lesion had worsening of his symptoms after surgery, however had improved to baseline at the time of discharge, and noticed significant improvement by 6 weeks postoperative, with some residual distal extremity weakness and hyper-reflexia. The patient with the intradural meningioma had complete resolution of weakness, persistent upper extremity hyper-reflexia, and diminished lower extremity position sense with left foot numbness. Mannion et al.⁵⁵ reported safe removal of intradural extramedullary tumors using a minimally invasive approach. A C6–C7 meningioma was removed from a 47-year-old female without complications. She was mobilized after 24 hours and was discharged home 2 days postoperatively. In their series, the minimally invasive approach was comparable to open surgery, without postoperative morbidity related to the approach. Zhang et al.⁵⁶ retrospectively reviewed 39 consecutive patients who underwent cervical intraspinal extramedullary tumor resection. These patients were divided into two groups, those undergoing a unilateral laminectomy or a partial unilateral laminectomy, and those undergoing a standard laminectomy. They reported positive clinical outcomes for the treatment of cervical intraspinal extramedullary tumors with a minimally invasive approach, including shortened operation time, decreased intraoperative blood loss, preservation of ligamentous and bony structures, and likely a reduced deformity rate. At 2 years follow-up, no patient in the hemilaminectomy or hemi-semi-laminectomy group had developed deformity.

The indications for a minimally invasive approach for the resection of spinal tumors have not been thoroughly evaluated. Contraindications include situations where dural resection is desired to achieve a complete resection, as the minimally invasive surgical window may not allow appropriate duraplasty to achieve a watertight closure. Tumors extending across more than two spinal levels are too large to be resected through a single MIS approach. One and two level extradural/intradural extramedullary spinal neoplasms can be resected through a MIS window without an increased risk for adverse neurologic complication. Minimally invasive surgery for the removal of tumors

will only have utility when the same surgical goals can be achieved despite a smaller surgical window, the risks of surgery to the patient are no greater than a traditional open approach, and that these techniques offer an advantage over open procedures.

Kypho- and vertebroplasty are widely accepted for treating patients with pathologic thoracolumbar lesions. These procedures can provide rapid pain relief and restoration of spinal stability. A transpedicular approach can be risky due to the anatomy of the cervical spine. A minimally invasive approach for anterior cervical kyphoplasty has also been described in the literature by Disch et al.⁵⁷ A C2 and C5 kyphoplasty was done using one minimally invasive anterior approach through a small incision. The procedure went uneventfully, and provided immediate pain relief and patient mobilization. Three-month follow-up showed an excellent outcome. In the future, kyphoplasty via a minimally invasive anterior approach may be a feasible, successful, and safe surgical method in the palliative treatment of metastatic disease.

KEY POINTS

- Minimally invasive foraminotomy is an excellent alternative to anterior cervical discectomy in the treatment of unilateral radiculopathy due to foraminal disc herniation or foraminal stenosis from cervical spondylosis.
- Posterior cervical foraminotomy does not consistently treat motor weakness from foraminal compression that is not associated with pain.
- Anterior cervical foraminotomy requires good preoperative planning to locate the position of the vertebral artery prior to decompression.
- Anterior cervical foraminotomy is more effective in cases of significant anterior spurs and in cases of posterolateral disc osteophyte complexes causing spinal stenosis.
- An operating microscope or endoscope is necessary in both procedures to enhance the visualization in the operating field.

INTRODUCTION

Thoracic spine disease due to its anatomical constraints has historically posed a dilemma when choosing a surgical approach. A variety of anterior and posterior open techniques have been previously described. Thoracic laminectomies were used historically with poor results due to spinal cord manipulation.¹ Posterior approaches to the thoracic spine include the transpedicular, costotransversectomy, and lateral extracavitary approaches. All of these approaches typically only allow a very limited working window.²⁻⁷ Anterior approaches were later developed to allow direct access to the vertebral column. Commonly used anterior approaches include transthoracic and lateral retropleural thoracotomy; however, approach-related morbidity is still high.⁸⁻¹⁰ Anterior approaches require double-lumen intubation with single-lung ventilation during the procedure as well as postoperative chest tube drainage.¹¹ Open approaches have demonstrated increased rates of infection, intercostal neuralgia, post-thoracotomy pain syndrome, diaphragmatic injury, and pulmonary complications.^{12,13} Post-thoracotomy pain syndrome has been reported in up to 50% of patients.¹⁴ In the early 1990s, McCormick popularized the lateral retropleural approach to the anterior thoracic spine.¹⁵ In order to minimize the

approach-related morbidity, minimally invasive techniques have been developed.

Minimally invasive surgical (MIS) techniques have been present for decades, but their application to the thoracic spine has only recently become popular.¹⁶ Thoracoscopic surgery was first performed in the early 1990s in order to complete vertebral biopsies, thoracic discectomies, and thoracic sympathectomies.^{17,18} Despite limited data, early reports on both thoracoscopic and MIS techniques have found comparable clinical outcomes to traditional open procedures.¹⁹ Benefits of muscle-sparing approaches include diminished blood loss, expedited recovery, less postoperative pain, and decreased hospitalization.^{8,9,19,20}

INDICATIONS

Minimally invasive surgical and thoracoscopic indications are the same as for traditional open approaches to the thoracic spine. Thoracic discectomy and corpectomy is indicated in cases of infection (e.g. osteomyelitis or spondylodiscitis), primary or metastatic tumors, unstable fracture patterns, and large symptomatic disc herniations.^{20,21} The mini-open lateral retropleural or anterolateral thoracoscopic approach for corpectomy and fusion are ideally

suited for 1–2 level procedures.^{15,22} The superior anterior thoracic spine remains a difficult region to access as the scapula limits a lateral approach and the superior mediastinum obstructs an intrathoracic approach.^{20,23} Abduction of the arm by 90–110° may allow lateral access as high as T3.¹¹

PATIENT EVALUATION

Evaluation of a patient for a minimally invasive discectomy and corpectomy should focus on the nature and location of the patient's complaints as well as comorbidities. Preoperative pulmonary function is critical to address as pre-existing lung disease may lead to significant complications. Patients with pre-existing pulmonary conditions may benefit from an extracavitary approach as single-lung ventilation is not routinely used.²⁰ A history of a prior thoracotomy, chest trauma, chest tube placement or thoracic spine surgery may relegate a minimally invasive approach unfeasible due to significant scarring or pleural adhesions.⁸

Patients may present with signs of axial discomfort, radiculopathy, and/or myelopathy.²⁴ Neurological examination focusing on sensory levels and lower extremity motor strength is essential for patients with thoracic spine pathology. Rectal tone should be assessed and sacral sparing identified if there is any neurologic deficit.

Preoperative evaluation focuses on the vertebral level of the disease and its relationship to the vasculature.¹⁸ Location of the heart, great vessels, and diaphragm play a role in choosing the laterality of the approach. In the upper thoracic spine, a right-sided approach is preferred, thereby avoiding the aortic arch and descending aorta. The diaphragm, liver, and inferior vena cava are at risk at lower levels, and therefore, a left-sided approach is preferred. The proximal thoracic spine is inaccessible via an MIS approach due to the mediastinum, scapula, and shoulder girdle, limiting access to the vertebral bodies of T1–T3.^{11,20}

POSITIONING

The lateral decubitus position is preferred for both MIS and thoracoscopic approaches (Fig. 131.1). Laterality of the approach depends on the location of the pathology. A right-sided approach (left lateral decubitus) may be easier to gain access to T4–T9 vertebrae by avoiding the mediastinal structures. A left-sided approach (right lateral decubitus) is preferred for access to T10–L2 as the aorta is easier to mobilize than the inferior vena cava.^{11,25} The patient is positioned such that the break in the table is at the

Fig. 131.1: Lateral decubitus positioning on a Jackson table.

operative level. A bump is also placed at the affected level to allow maximal flexion.²⁶ An axillary roll is placed to avoid brachial plexopathy and the arms are flexed forward. The knees and ankles are well padded to relieve pressure to the peroneal nerve and malleoli. The pelvis and upper thorax are taped to allow flexion without moving the patient.²⁶ The surgeon is positioned dorsally and the fluoroscopic C-arm and mounted retractor arm are ventral to the patient. The tubular retractor is placed such that the open end faces the spinal canal/cord, allowing an unobstructed view of the neural compression. The patient is draped for a thoracotomy in case conversion to an open procedure is necessary.

TECHNIQUE FOR TRANSTHORACIC THORACOSCOPIC APPROACH

Anesthesia is induced with a double-lumen intubation. The patient is then repositioned in the lateral decubitus position. Anteroposterior (AP) and lateral fluoroscopy are used to mark the vertebral level and the anterior/posterior margins of the vertebral column on the lateral chest wall.¹⁸ The four portal incisions are then marked around the level of interest (Fig. 131.2). The working portal is centered at the level of the index vertebral body just posterior to the posterior axillary line.⁷ A portal for the endoscopic camera is marked two or three intercostal spaces directly above or below the working portal. The camera is placed superior to the working portal to view lower thoracic levels and inferior to the working portal to view upper levels.¹⁸ The two additional portals are used for suction/irrigation and retraction along the anterior axillary line.

Fig. 131.2: Intraoperative photograph depicting thoracoscopic portal placement.

Source: Reprinted with permission from Beisse R, Trapp O. Thoracoscopic management of spinal trauma. *Oper Tech Neurosurg.* 2005;8(4):205-13, Elsevier.

Single-lung ventilation is initiated by the anesthesiologist. A 10 mm incision in line with the rib is made at the superior portal. The intercostal muscles are bluntly dissected until the rib is identified. A curved clamp is placed superior to the rib penetrating the pleural cavity. A finger is inserted into the chest to feel for any pleural adhesions. A cannula is placed into the chest followed by a 30° endoscope. The pleural space is examined for adhesions, deflation of the lung is confirmed, and the great and intercostal vessels are identified. The remaining three portals are placed under direct endoscopic visualization.¹⁸ A fan retractor is placed in the inferior portal to protect to the deflated lung and diaphragm.

The intrathoracic location of the disc space and vertebrae are identified under fluoroscopy. A harmonic scalpel is used to incise the overlying pleura. A flap is lifted exposing the lateral vertebral body and rib head. In cases at or below the thoracolumbar junction, the diaphragmatic insertion needs to be incised and lifted from the vertebral bodies.²⁷ The segmental artery is exposed, ligated with vascular clips, and coagulated with bipolar cautery. Ligation of the segmental artery is a crucial step when performing a corpectomy as uncontrolled bleeding may necessitate conversion to an open procedure.¹⁸ Some surgeons prefer placing K-wires or screws to use as fixed landmarks in the vertebral bodies above and below the level of the corpectomy.²⁷ The intervertebral discs are then excised with a rongeur and curette. The central portion of the vertebral

body is removed using a high-speed burr. The anterior and posterior vertebral body walls are initially preserved to protect the spinal canal. The proximal rib head is excised exposing the underlying pedicle. The pedicle is then resected in order to decompress the spine. The remaining posterior vertebral body is resected completing the decompression.

An expandable titanium cage is placed in the defect and expanded under fluoroscopic guidance. Posterior instrumentation via pedicle screws may also be performed through separate posterior incisions. The diaphragm is repaired endoscopically if needed. A chest tube is placed through the working portal. Reinflation of the lung is monitored under direct visualization. The remaining cannulas are removed and the portal incisions are closed in layers.²⁷

CONSIDERATIONS AND COMPLICATIONS OF THORACOSCOPY

Thoracoscopic surgery of the spine can be performed safely in the hands of an experienced surgeon. Advantages to this technique include a direct trajectory to the anterior thoracic spine, minimal tissue and rib retraction, decreased postoperative pain, and shorter hospitalizations.²⁸ The rate of approach-related complications has been reported as 1.3–5.7% in several large studies.^{27,29,30} Serious complications related to thoracoscopy exist including injury to the great vessels, postoperative diaphragmatic hernias, and splenic laceration.^{27,31} Manipulation of long endoscopic instruments while operating with two-dimensional visual cues may lead to a significant learning curve.

Pulmonary complications are often associated with thoracoscopy. Complications of single-lung ventilation and inadvertent lung injury are important to consider. Double-lumen intubation is more challenging for the anesthesiologist. Improper placement, inaccurate tube diameter, and incomplete obstruction of the operative lung can lead to air leaks into the deflated lung placing it at risk of injury. The duration of single-lung ventilation is typically longer for spine surgery than most thoracoscopic procedures. Prolonged periods of nonventilation may cause an accumulation of bronchial secretions in the deflated lung. If the secretions are not cleared properly they can lead to postoperative atelectasis and pneumonia. Therefore, an aggressive postoperative respiratory therapy regimen is essential.³² Iatrogenic atelectasis during thoracoscopy also leads to a ventilation-perfusion mismatch that may cause arterial desaturation, CO₂ retention, and respiratory acidosis.^{31,32}

Fig. 131.3: Intraoperative photograph demonstrating exposure of the pleura. Approximately, 2 cm of the rib has been removed and the pleura is visible in the center of the wound.

Thoracoscopic instruments may also lead to complications. The trocars should be placed gently to avoid injury to the intercostal nerves and resultant intercostal neuralgia. Some surgeons recommend the use of soft trocars to reduce stress on the nerve, as they are manipulated during surgery.¹⁰ The proximity of the lung, large vessels, diaphragm, and organs immediately beneath the diaphragm requires caution when placing the trocars.²⁷ Injury to the lung parenchyma may lead to persistent air leaks.

TECHNIQUE FOR MINI-OPEN LATERAL RETROPLEURAL APPROACH

Anteroposterior (AP) and lateral views are obtained with fluoroscopy. The operative level is identified and the anterior and posterior margins of the vertebra are marked. A 3–4 cm incision is made at the midaxillary line directly over the index vertebra in the direction of the rib.¹¹ The rib is exposed subperiosteally, reflecting the neurovascular bundle inferiorly. A 2 cm segment of rib directly overlying the vertebra is removed and set aside for use as autograft (Fig. 131.3).^{8,26} At this point, the parietal pleura is exposed. The plane between the pleura and endothoracic fascia is developed with a sponge stick, peanut or with a fingertip.^{8,26} Once the lateral vertebral body is reached fluoroscopy is utilized to place a series of tubular dilators through the defect, sweeping the pleura, and lung anteriorly.²⁶ An expandable split-blade retractor is placed over the dilators and secured to the flexible table-mounted retractor arm (Fig. 131.4).

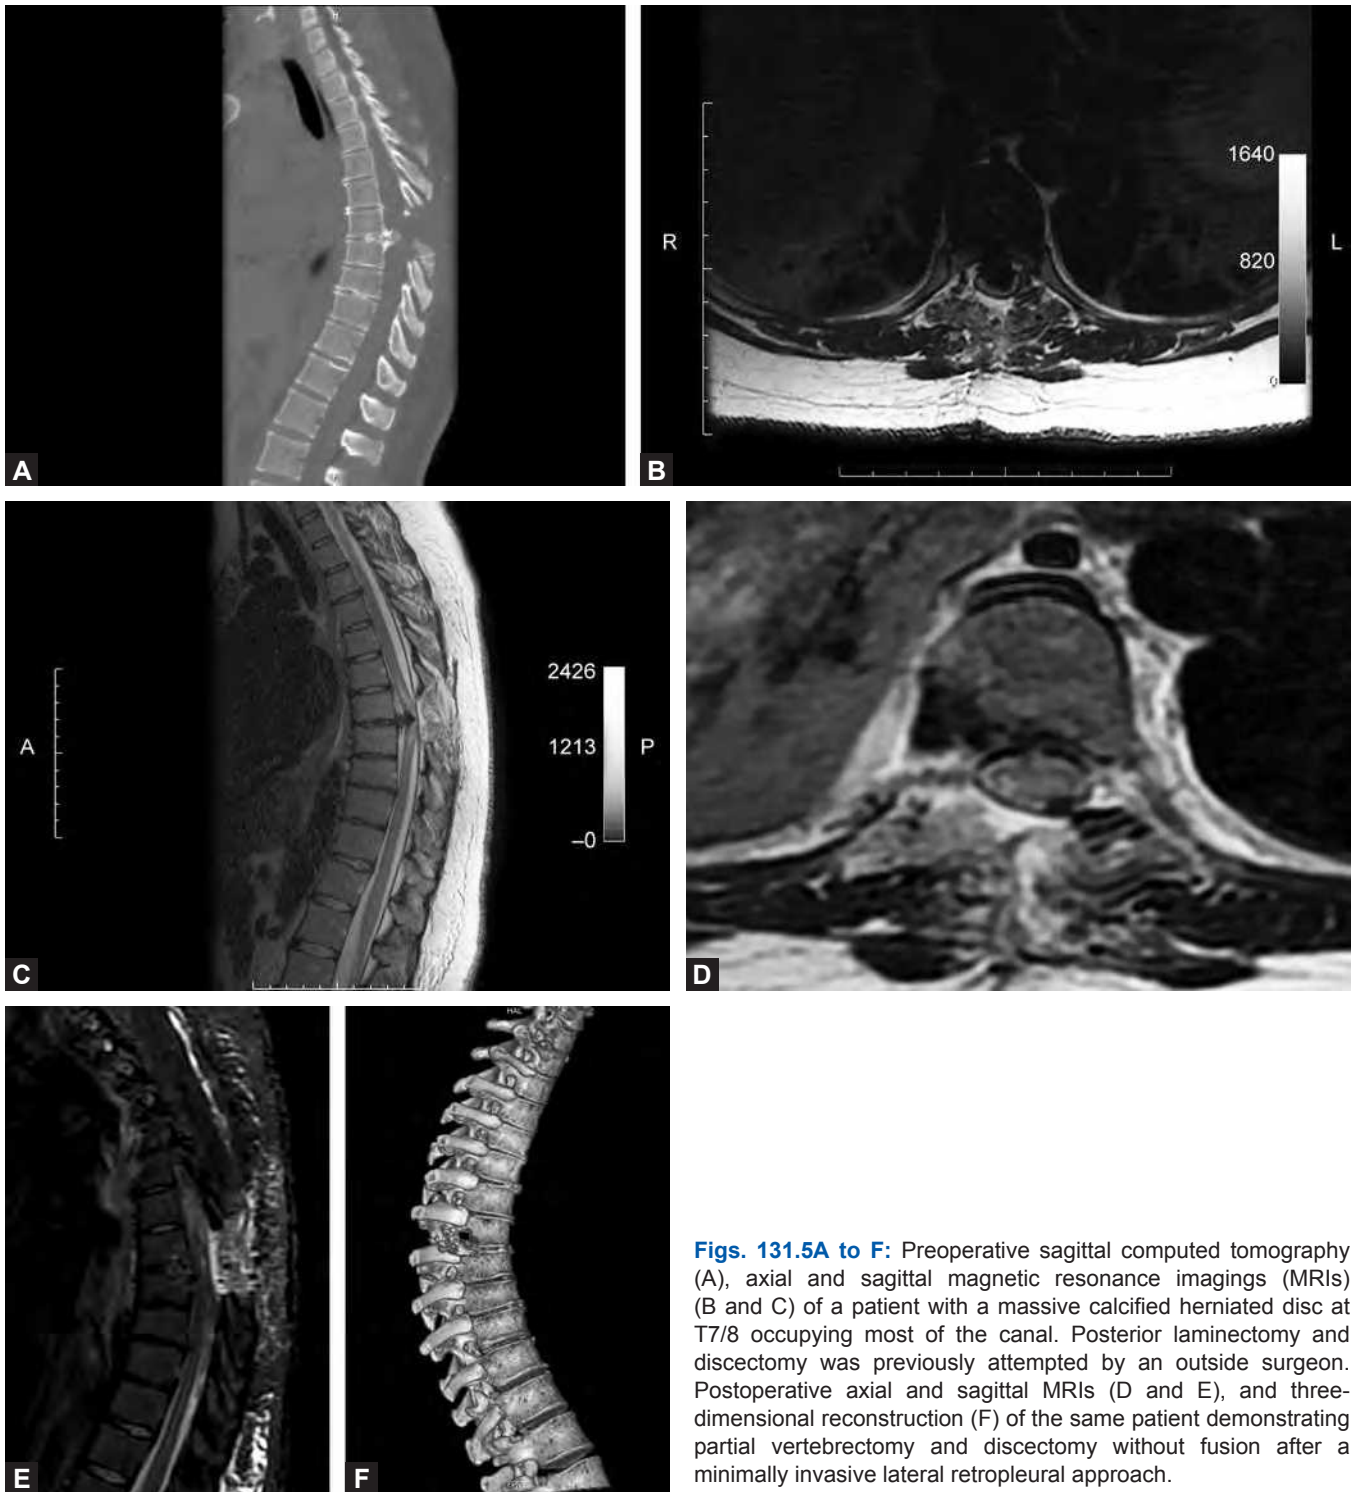

Fig. 131.4: Photograph of the tubular dilators and table-mounted retractor arm in place.

Discectomy

When performing a thoracic discectomy, a trough is created anterior to the canal by drilling the posterior third of the vertebral body adjacent to the disc space (Figs. 131.5A to F).⁷ A thin shell of the posterior vertebral body with the herniated disc is left in place protecting the dura. The shell and herniated disc are then removed by gently pulling anteriorly into the trough, thereby dissecting away from the dura and spinal cord. Large calcified herniated discs may be adhered to the posterior longitudinal ligament (PLL) and dura that may lead to inadvertent durotomy during the discectomy.^{6,11} Using a high-speed burr to create a cavity and to decrease the size of the calcified disc may decrease thoracic cord compression while obviating the need to detach the calcific disc from the adhered dura. Fusion is not necessary in most cases. However, if large portions of the vertebral bodies are removed, then the resected segment of the rib may be used as an autograft.⁷

Corpectomy and Fusion

The vertebra and intervertebral discs above and below are subperiosteally exposed (Fig. 131.6). The segmental artery is cauterized and resected as proximally as possible.^{8,26} The rib head at the corresponding vertebra and possibly caudal vertebra need to be identified and excised to fully expose the vertebral body, pedicle and adjacent intervertebral discs.²¹ The pedicle is removed using a high-speed burr and Kerrison rongeur to gain entrance into the canal,

Figs. 131.5A to F: Preoperative sagittal computed tomography (A), axial and sagittal magnetic resonance imaging (MRIs) (B and C) of a patient with a massive calcified herniated disc at T7/8 occupying most of the canal. Posterior laminectomy and discectomy was previously attempted by an outside surgeon. Postoperative axial and sagittal MRIs (D and E), and three-dimensional reconstruction (F) of the same patient demonstrating partial vertebrectomy and discectomy without fusion after a minimally invasive lateral retropleural approach.

exposing the lateral dura, and exiting nerve roots.^{8,21,22} A discectomy is then performed using angled curettes and a pituitary or Kerrison rongeur. The borders of the vertebral

body to be excised are clearly visible. The corpectomy is then carried out using a high-speed burr, rongeurs, and curettes until a thin portion of the anterior vertebra is

Fig. 131.6: The thoracic vertebral body to be resected is exposed subperiosteally.

Fig. 131.7: Intraoperative photograph demonstrating a corpectomy. The lateral vertebral body has been resected and tumor is present within the corpectomy site. The anterior longitudinal ligament is intact at the top of the photograph.

Fig. 131.8: The expandable titanium cage has been placed into the defect. Anterolateral plates are placed in the vertebral bodies above and below.

preserved with the anterior longitudinal ligament (ALL) (Fig. 131.7).²⁶ The PLL may be left intact if it is not involved in the compressive pathology.²¹

An expandable titanium cage is sized and inserted into the defect and expanded until appropriate sagittal alignment is attained.^{11,26} Anterolateral plating of the adjacent vertebrae and a connecting dual rod construct may be used to achieve fixation (Fig. 131.8).²⁶ A posterior percutaneous pedicle screw-rod complex may also be used to achieve fixation and is placed in either the lateral decubitus position or after the patient is repositioned prone on the Jackson table.^{9,33} The retractor is removed and the pleura is

evaluated for tears. Placement of a chest tube is not necessary, if the pleura is not violated.

CONSIDERATIONS AND COMPLICATIONS OF MINI-OPEN LATERAL RETROPLEURAL APPROACH

At the onset of the procedure, it is essential to obtain high-quality orthogonal fluoroscopic views when marking the vertebral borders as parallax may result in improper dilator placement.²⁶ Anterior displacement of the dilator may result in resection of the ALL or damage to the great vessels.

Bleeding from the segmental artery is sometimes encountered after cauterization. Ligation can be difficult through the minimal access portal; however, hemostatic agents, and pressure will usually achieve hemostasis.²⁶ It is important to resect the segmental artery prior to beginning the corpectomy, as bleeding can be brisk.²¹ Any remaining bleeding may then be controlled with bone wax or a gelatin sponge.¹¹

Overall complication rates related to the MIS lateral retropleural approach are reported from 12.5% to 15.4%.^{6,11,33,34} Pleural tears are the most common complication encountered through the MIS lateral retropleural approach. Pleural tears occurred in 11 of 38 (28.9%) patients in a series by Scheufler. Tears in eight patients were repaired primarily without a subsequent pneumothorax, while three patients

required placement of a chest tube.¹¹ The surgeon must be cognizant of this risk and be prepared to place a chest tube or red rubber catheter at the end of the procedure to treat the iatrogenic pneumothorax.²⁶ Patients with osteomyelitis or metastatic disease may have marked paraspinal pleural reactions with adhesive thickening that can distort the interfascial planes increasing the risk of pleural tears.⁸ Additional complications are similar to the open or endoscopic approaches and include infection, migration of the implant, dural tears, intercostal neuralgia, postoperative atelectasis, pneumothorax, or pleural effusions.

OUTCOMES

In recent years, there have been numerous articles evaluating the utility of a mini-open and thoracoscopic approach to the thoracic spine. Early cohorts are promising for the minimally invasive techniques in the setting of trauma, infection, neoplasm, and disc herniations.^{6,8,11,27,29,30,33-39} Khoo et al. reported results of 371 patients who underwent thoracoscopic corpectomy and fusion for thoracolumbar fractures.³⁰ The authors demonstrated a significant learning curve for the thoracoscopic technique; average operative time initially was 300 minutes but later decreased to 180 minutes with experience.

Quint et al. reported outcomes of 167 patients who underwent thoracoscopic single-level discectomy without fusion and found good to excellent outcomes in approximately 80% of patients in regards to pain and motor function.³⁵ The complication rate in this cohort was 15.6% with three patients (1.8%) requiring reoperation due to severe pain from segmental instability after the discectomy. The authors also demonstrated complete decompression on postoperative computed tomography in 98% of patients.

The MIS lateral retropleural approach for thoracic discectomy and corpectomy is gaining popularity (Table 131.1).^{6,11,33,34,36,37} Smith et al. reported a series of 52 patients treated with corpectomy and fusion for thoracolumbar burst fractures.³³ Of the patients presenting with acute neurologic deficit after trauma, 94.2% demonstrated trends toward significant improvement in the ASIA (American Spinal Injury Association) classification at 1 year follow-up. Sheufler's series of 38 patients demonstrated successful fusion at 1 year in 8 of 10 (80%) patients treated for infection or fracture, but only 14 of 28 (50%) of patients treated for metastatic neoplasm.¹¹ Both studies found a significant reduction in operative time, decreased

blood loss, and shorter hospitalizations using the MIS approach when compared to an open procedure.^{11,33}

There are several studies reporting on the outcomes of MIS lateral retropleural discectomy for symptomatic thoracic disc herniations (TDH).^{6,36,37} Uribe et al. compared their results to a review of the literature on reported open surgeries and found a trend toward shorter operative times (182 versus 229.3 minutes), reduced blood loss (290 vs 562.9 mL), and fewer hospitalization days (5.0 vs 8.6 days) in their MIS group.⁶ The rate of complications was also significantly lower in the MIS group compared to the open group (15% vs 36.7%). Kasliwal et al. reported on seven patients after a mini-open discectomy for symptomatic TDH and found myelopathy improved in three out of seven patients and radicular pain improved in four out of four patients.³⁷ Moran et al. reported results of MIS lateral retropleural discectomy without fusion in 17 patients with large calcified TDH and myelopathy.³⁶ Outcomes demonstrated improvement on the Frankel Grading system in 76% of patients at 2-year follow-up. The Oswestry Disability Index (ODI) also improved from 38% to 21% at 2-year follow-up. In this study, there was no postoperative kyphosis or evidence of collapse in any patient treated with single-level discectomy alone without fusion.

CONCLUSION

The potential for the minimally invasive techniques for thoracic spine surgery to improve postsurgical outcomes is promising. Both the transthoracic thoracoscopic and minimally invasive lateral retropleural approaches allow excellent visualization of the anterior thoracic vertebrae. Corpectomies and discectomies performed through traditional open approaches are associated with significant morbidity and increased rates of complications. Thoracoscopic approaches have minimized the morbidity of open approaches but still require intrapleural access with single-lung ventilation and chest tube placement. The MIS lateral retropleural approach obviates the need for a chest tube, but pleural tears are common and must be addressed when they occur. There is a steep learning curve with both MIS and thoracoscopic techniques and the surgeon must be familiar with the applied anatomy, special equipment, and unique complications associated with each approach. Minimally invasive thoracic spine surgery offers the benefits of direct access to the anterior column for conventional discectomy and corpectomy while minimizing incisional trauma and tissue dissection.

*Baaj et al.³⁴ reported on complications in a cohort of patients that overlaps with patients reported by Smith et al.³³

KEY POINTS

- Minimally invasive surgery of the thoracic spine is a developing field indicated for the treatment of fractures, infections, neoplasm, and disc herniations causing cord compression.
- Discectomy with or without fusion and corpectomies with anterior reconstruction can be successfully performed with minimal approach-related trauma to the surrounding tissues.
- Both the thoracoscopic transthoracic and minimally invasive lateral retropleural techniques have demonstrated comparable clinical outcomes when compared to traditional open approaches.
- Benefits of minimally invasive spine surgery include decreased blood loss, postoperative pain, hospitalizations and complications.
- There is a steep learning curve that the surgeon must overcome in order to fully appreciate the benefits of the minimally invasive techniques.

INTRODUCTION

The pathophysiology and natural history of degenerative disc disease was first explored by Kirkaldy-Willis in the 1970s through a study of autopsy specimens of the human spine.^{1,2} Disc dysfunction and herniation were proposed to be the initial events in the degenerative cascade, with the end result being spinal canal stenosis.

Disc herniation is the posterior protrusion, or in severe cases, extrusion of the nucleus pulposus through a tear in the annulus fibrosus often leads to irritation and compression of nerve roots. This is usually manifested by pain and/or weakness in the area of distribution of the affected nerve(s). The pain in the lower limbs is often sharp and shooting in nature and in some instances can be crippling, adversely affecting the patient's normal daily activities and leading to functional decline. Initial treatment options include pain medication, anti-inflammatory agents, physical therapy, and in some cases, epidural corticosteroid injections. When conservative treatment methods fail, open surgery is considered. Surgical options include laminectomy with discectomy, laminotomy with discectomy, and microsurgical discectomy (MSD). However, open surgical procedures are associated with many drawbacks—notably soft tissue injury from the large skin incision and subcutaneous dissection, stripping of paraspinal muscle attachments, as well as trauma to the muscles from the retraction required for adequate visualization.^{3,4} In addition, the need for cauterization of blood vessels over a large area

of exposure may further hinder the blood supply and healing of the paraspinal muscles.

Degenerative lumbar spinal stenosis is one of the leading indications for spinal surgery in the elderly. This disease results from compression of the dural sac and nerve roots secondary to a summation of degenerative changes such as intervertebral disc bulging or herniation, ligamentum flavum buckling, facet joint hypertrophy, and osteophyte formation. Affected patients have diminished standing and walking tolerance, mostly attributable to a reduction in the spinal canal diameter and cross-sectional area. Clinical symptoms include a claudication type pain in the lower back and legs and sometimes associated motor and sensory deficits.⁵ These symptoms are more pronounced in extension, and activities that involve spinal flexion, such as sitting, walking uphill or leaning forward on a shopping cart, can often partially alleviate symptoms.⁵⁻⁷

Traditional open surgery performed to relieve lumbar stenosis involves an open bilateral laminectomy to achieve a wide decompression. This is typically accompanied by decompression of the medial portion of the facet joints, including the lateral recesses, to free the neural elements.⁸ Open approaches such as these are well established for relieving the symptoms of nerve compression. However, there are potential risks and complications such as blood loss, postoperative pain, and iatrogenic spinal instability. For elderly patients, these factors can be particularly concerning due to comorbidities and a lower cardiopulmonary reserve.^{9,10} Also, postoperative analgesia must be used carefully in the elderly due to reduced hepatorenal function.

Fig. 132.1: An illustration depicting Kambin's triangle used for posterolateral transforaminal approaches to the disc space.

All of the afore-mentioned concerns with open surgery have driven a need for less invasive exposures. Minimally invasive spine surgery (MISS), consisting of techniques utilizing special instruments that enable surgeons to operate through smaller incisions and focused surgical corridors, has emerged as a rapidly expanding field in spine surgery.

EVOLUTION OF MINIMALLY INVASIVE SPINE SURGERY

The concept of MISS originated from early experiments with chymopapain by Smith et al. in 1963.¹¹ These authors were the first to inject chymopapain into the nucleus pulposus of intervertebral discs in patients with sciatica to achieve chemonucleolysis (disc dissolution). Later in 1975 Hijikata et al.^{12,13} and in 1983 Kambin and Gellman¹⁴ independently described percutaneous discectomies via a posterolateral approach to the spine. They utilized an approach through a neurological “safe zone” overlying the dorsolateral aspect of the disc, now known as Kambin's triangle (Fig. 132.1). This triangle consists of an area between the right angle formed by the superior endplate of the caudal vertebral body and the dura/traversing nerve root, with the exiting nerve root forming the hypotenuse.¹⁵ These procedures were initially performed by passing a cannula under fluoroscopic control into the intervertebral disc (through Kambin's triangle) and using nucleotomes and long pituitary rongeurs to remove the disc fragments percutaneously. With technological advancements in fiber-

Fig. 132.2: The posterior interlaminar approach to the spine compared to the posterolateral transforaminal approach. [(PELD: Posterolateral endoscopic lumbar disectomy; MED: Microendoscopic discectomy)]

optics and video imaging, newer sophisticated endoscopes were developed. In 1997, Yeung¹⁶ introduced the first working channel endoscopic system for commercial distribution, known as Yeung Endoscopic Spine Surgery (Richard Wolf Surgical Instruments, Vernon Hills, IL, USA). Minimally invasive spine surgery using this endoscopic posterolateral transforaminal approach to the intervertebral disc has come to be known as PELD (posterolateral endoscopic lumbar disectomy).

Following the trend of smaller incisions, in 1997, Foley and Smith¹⁷ developed a novel minimally invasive posterior paramedian approach to the spinal canal for disc disease, similar to that used in open MSD. In contrast to the micro-lumbar procedure, access to the interlaminar space was achieved through serial dilation over a guidewire using sequentially sized cannulas, and finally a tubular retractor, to expose the operative window. An endoscope passed through the retractor was utilized to visualize the surgical field.¹⁸ This MISS technique digressed from the above-mentioned posterolateral approach and is often referred to as microendoscopic discectomy (MED). Here, a posterior interlaminar approach was employed to access the spinal canal and disc (Fig. 132.2). Subsequent refinements to the technique and development of better instrumentation led to the second-generation MED system in 1999, called METRx (Medtronic Sofamor Danek Inc, Memphis, TN, USA). The second-generation systems provided improved three-dimensional visualization using an operative microscope. Another popular MED system is the Destandau Endospine system (Karl STORZ GmbH & Co KG, Tuttlin-

gen, Baden-Württemberg, Germany) which incorporates a cone shaped, free-hand working channel type of assembly.^{19,20}

Anterior laparoscopic and retroperitoneal endoscopic approaches²¹⁻²³ to the spine, as well as lateral transpsoas approaches,^{24,25} have also been developed and are used for lumbar interbody fusion procedures. However, description of these approaches and their applications to MISS is beyond the scope of this chapter.

Given the diverse nature of approaches, techniques and instrumentation systems developed to advance the practice of MISS, there is a consistent underlying philosophy: preservation of the structural integrity and function of the lumbar paraspinal muscles as much as possible. A brief description of the anatomy of the paraspinal muscles and their function is essential to understand this rationale.

Lumbar Paraspinal Musculature and the MISS Rationale

The erector spinae group that comprises the intrinsic musculature of the lumbar spine consists of the multifidus, longissimus and iliocostalis muscle subsets. Due to their medial location and unique architectural anatomy, the multifidus group contributes to important biomechanical characteristics of the spine. The multifidi are believed to be the major posterior spinal stabilizing muscles due to comparatively larger physiological cross-sectional area and shorter fiber length, enabling them to generate greater forces over relatively short distances.^{26,27} Biomechanical studies have demonstrated that the multifidus opposes the counter-rotation force generated by the abdominal musculature on the lumbar vertebrae. Thus these muscles play a vital role in maintaining truncal stability in concert with the abdominal muscles.²⁸ However, multifidi are also the muscles that suffer most of the injury during dissection and retraction in open posterior lumbar surgeries.

The multifidus also has a unique nerve supply without any additional intersegmental collaterals, in contrast to the other lumbar paraspinal muscle groups. This unisegmental innervation is derived from the medial branches of the dorsal rami, which at each level, course through a groove between the mammillary and accessory processes. Here, these nerves branch and become relatively fixed by the fibro-osseous mamilloaccessory ligament. This predisposes them to injury with wide midline dissection and retraction during open posterior approaches.^{29,30} To address this issue, a paramedian approach along the interfascial plane between the multifidus and the longissimus muscles, like that described by Wiltse et al.,³¹ is employed in posterior

MIS surgery. This limited dissection is reported to result in better preservation of the vascularity of the paraspinal muscles and reduced postoperative ischemic necrosis and scarring. Apart from minimizing soft tissue and paraspinal muscle injury, MISS techniques aim to preserve the osseoligamentous posterior elements as much as possible. Conventional open surgical approaches resect the lamina and spinous processes to gain access to the spinal canal and the disc space. This leads to detachment of the multifidus and the supraspinous/infraspinous ligaments. With the use of MISS techniques and by limiting bony resection to laminotomies, spinal motion segment stability can be maintained by preserving these soft tissues and osseoligamentous structures.

Intraoperative retractor-induced injury to the paraspinal muscles has been studied by numerous investigators.³²⁻⁴² Intramuscular pressures as high as 158 mm Hg have been reported in the erector spinae group intraoperatively while using various self-retaining retractors.⁴² These retractors exert constant point pressure on the tissues to stay anchored in position. This nonuniform pressure, applied mostly at the edges of the exposed incision and the underlying paraspinal muscles, leads to impediment of local blood flow and subsequent ischemic muscle necrosis. In contrast, tubular retractor systems developed for the MED MISS procedures have been shown to exert significantly lower pressure on the surrounding paraspinal muscles. This could be attributed to the uniform cylindrical geometry that minimizes the pressure per unit area while maximizing the surface area of contact. The intramuscular pressures in the vicinity of tubular retractors decreases quickly after removal of the initial expanders, whereas open retractor continue to exert high pressures on the surrounding muscle when deployed.⁴¹ In addition to maintaining uniform pressure on the surrounding tissue throughout the procedure, tubular retractors can be mounted to the operative table with special assemblies.⁴³

Thus, the technique of MISS has been developed with the above-mentioned anatomical and biomechanical considerations and instrumentation design factors. In addition to tubular retractors, some of the technological discoveries that have contributed to MISS include innovations in spinal imaging techniques, fiberoptic lighting and image recording technologies, and operative microscopes and endoscopes with working channels.⁶

The tubular retractor-assisted microendoscopic MISS, which was initially devised and used for lumbar discectomies, has found increasing applications in recent years. Some of these include decompression for lumbar canal

Fig. 132.3: A serial dilator assembly used to bluntly separate the paraspinal muscle fibers.

stenosis, minimally invasive instrumented lumbar fusion procedures such as PLIF (posterior lumbar interbody fusion) and TLIF (transforaminal lumbar interbody fusion), and intra and extradural spine tumor resection procedures.⁴⁴

TUBULAR RETRACTOR-ASSISTED MINIMALLY INVASIVE SPINE SURGERY

Surgical Approach

With the patient prone on the operating room table, the hips are placed in flexion to decrease lumbar lordosis and to allow expansion of the interlaminar spaces that increases the working area for tubular retractor placement. The incision site is identified about 15 mm from midline on the side of the pathology, and C-arm fluoroscopy is used to confirm position over the correct disc space. A 15–20 mm incision is made longitudinally through the skin and subcutaneous tissue, and the lumbodorsal fascia is incised. A guidewire or pin is advanced through the incision to reach the base of the superior lamina at the junction of the facet joint. The position of the wire is confirmed again in both anteroposterior and lateral fluoroscopic views. Serial dilators of sequentially incremental diameters are then threaded over the guidewire. This ensures that the paraspinal muscles fibers are separated gradually and bluntly rather than being cut (Fig. 132.3). This technique allows for minimal stripping of the muscles from their attachment sites and helps preserve the vascularity and innervation.

Fig. 132.4: An intraoperative fluoroscopic view confirming proper retractor placement.

The tubular retractor is then advanced over the final dilator, down to the lamina, ensuring that soft tissues and muscles do not get pinched in between. The position is again confirmed fluoroscopically (Fig. 132.4). The retractor is then connected to the flexible arm assembly mounted to the operating table to maintain position and prevent migration (Fig. 132.5). An endoscope or an operating microscope can be used through the tubular retractor and the procedure is performed using modified long-handled instruments such as rongeurs, disc forceps, curettes, and retractors (Figs. 132.6 and 132.7).

The tubular retractor system offers direct visualization of the operative field. However, the relatively limited field of view requires a high degree of anatomical familiarity and 360° degree orientation. To access adjacent spinal levels through the same skin incision, a wand maneuver can be performed (Fig. 132.8). This is accomplished by releasing the holder that mounts the tubular retractor to the operating table and introducing a wider dilator. The dilator can be used as a handle to reposition the retractor to an adjacent interlaminar space. The retractor is then secured again to its table mounted assembly.⁴⁵ The retractor can similarly be angled across midline, enabling the surgeon to reach a contralateral disc herniation. However, performing MISS through one small incision using a single retractor poses technical difficulties in approaching more than two adjacent segments. This limits the utility of tubular retractor-assisted MISS to procedures performed over

Fig. 132.5: A table-mounted flexible arm assembly connected to a cannula to maintain the retractor position intraoperatively.

Fig. 132.6: Instruments inserted through a cannula to perform a discectomy.

Fig. 132.7: A modified Kerrison rongeur passed through a retractor to remove soft tissue and bone piecemeal.

relatively short segments of the spine. After the surgery has been completed, the tubular retractor is removed and the muscles close upon each other in the potential space that the retractor previously occupied, thus limiting muscle damage compared to open surgery.

Lumbar Discectomy Using Tubular Retractors

Once the lamina has been reached by the technique mentioned above, removal of the overlying soft tissues is done through the tubular retractors with small rongeurs.

Fig. 132.8: The wandering maneuver enables the surgeon to modify the tubular retractor position in order to operate on adjacent spinal segments through one incision.

Adequate hemostasis is achieved with bipolar cautery forceps. The inferior edge of the superior lamina is identified and a laminotomy is performed, as well as a medial facetectomy in some cases. Bony resection is kept to a minimum while still providing adequate access to the disc

Fig. 132.9: An illustration depicting the effect of tube diameter and length on the degree of angulation that can be achieved by operative instruments passed through a tubular channel.

and the lateral recess. The ligamentum flavum is incised using special scissors and removed using modified rongeurs. The nerve root on the side of herniation is identified and exposed with gentle epidural dissection. After the nerve has been mobilized it can be retracted medially or laterally to access the prolapsed intervertebral disc. This is followed by discectomy using modified disc forceps, similar to an open microdiscectomy. Mobility and tension on the nerve root are reassessed and meticulous hemostasis is achieved before closure. The importance of hemostasis cannot be understated in minimally invasive procedures, as any significant residual bleeding after closure may lead to hematoma formation and compression of the neural elements. This problem is exaggerated by the relative lack of potential space for the hematoma to expand compared to traditional open exposures.

In general, a retractor with a tube diameter of 20 mm and a length of 40–50 mm is used for lumbar spine discectomy and decompression.⁴⁴ Utilizing the appropriately sized retractor is paramount as the surgeon might face technical difficulties introducing surgical instruments through a cannula that is too small in diameter or too long in length. Longer length tubes may be advantageous in obese patients, where there is a greater depth from the skin surface to the lamina. However, the length restricts the achievable degree of instrument angulation.⁴⁵ A shorter, large bore cannula provides a larger working area and permits a greater degree of angulation and mobility of instruments (Fig. 132.9). However, larger diameter tubes require increased soft tissue dissection and paraspinal muscle

Fig. 132.10: A root retractor passed outside a cannula to prevent muscle from creeping in the distal lumen of the retractor tube.

splitting. In addition, docking the wider object into the interlaminar space may be technically difficult. Larger diameter tubes may also facilitate increased muscle creep into the lumen of the tube's distal opening, thereby reducing visibility. Using a root retractor placed flush outside the tube can prevent the surrounding muscles from sliding inside, through the tip (Fig. 132.10).⁴⁴

Due to the limited operative window, it is critical that the size and location of the disc herniation be carefully assessed prior to surgical intervention. In many instances, with thorough planning and good surgical skills, one incision may be all that is required to access the spinal canal, the lateral recess, and the foraminal space for far lateral disc removal.⁴⁶

Decompression of Lumbar Spinal Stenosis

Minimally invasive spine surgery for lumbar spinal stenosis using tubular retractors was first reported in a series of patients by Khoo and Fessler in 2002.⁴⁷ The technique was termed microendoscopic decompressive laminotomy. This procedure differs slightly from the one described for MED in that the incision and approach are slightly farther from midline. This allows greater angulation of the tubular retractor, permitting access to the central and contralateral spinal canal for decompression. Angled curettes and Kerrison rongeurs are required to extend the decompression to the contralateral lateral recess and foramen. The extent of resection of the ligamentum flavum is also greater than

that performed in a MED. Bony resection of the undersurface of the contralateral lamina using specialized burrs and curettes is done to create more space in the spinal canal. Cases of adjacent multilevel stenosis addressed through a single incision have been reported.⁴⁷ Once adequate canal decompression is achieved, annulotomy and standard discectomy can be done if indicated. Hemostasis is obtained prior to closure to avoid serious complications such as epidural hematomas.

Complications

Dural tears and nerve root injuries are the most frequently occurring complications with tubular retractor-assisted MISS.^{48,49} In a systematic review evaluating complications of tubular lumbar decompression and fusion procedures, Fourny et al.⁴⁹ reported that the rates of dural tears and nerve root injuries from some studies were higher in the minimal access group compared to the open surgical group; however, overall the complication rates were similar between groups. Poor depth perception with endoscopic surgery has been postulated as one of the factors behind the higher incidence of these complications.⁵⁰ The steep learning curve for the procedure also likely contributes to higher rates of technique-related complications.⁵¹ Other infrequently reported complications include wound hematomas, seroma formation, and wrong level surgery.^{48,52} Wound hematomas can lead to serious neurological complications due to the finite space with no place to expand. This situation can be avoided by obtaining hemostasis before closure, and placing surgical drains if there are any doubts about the adequacy of hemostasis.

Recurrent herniations have also been reported to occur more frequently with microendoscopic discectomy compared to open procedures.⁵⁰ The restricted working area offered by the tubular retractors could affect the identification and thorough removal of free fragments within the intervertebral space, leading to recurrence.

Procedural Considerations

Advocates of the open discectomy and decompression procedures have consistently cited the increased radiation exposure and steep learning curve as drawbacks to the MISS techniques. In a recent prospective controlled trial, Mariscalco et al.⁵³ studied the radiation exposure to the surgeon during open and minimally invasive microdiscectomies using tubular retractors. They concluded that the radiation exposure in MISS procedures was significantly

higher, with exposure levels approximately 10–20 times greater than in open procedures. However, with the use of protective lead aprons and thyroid shields, they found that approximately 1,623 MISS procedures could be performed per year before exceeding the permissible whole body radiation occupational exposure limits. Thus, despite the heightened radiation exposure levels, MISS MED appears to be a relatively safe procedure if appropriate protective equipment is worn. To further reduce radiation exposure levels, measures such as the “hands off” technique (removing one’s hands from the operative field and the vicinity of the radiation beam) during fluoroscopy and standing on the side opposite the fluoroscopy source are recommended.⁵³ The use of emerging technologies, such as navigation assisted fluoroscopy, have the potential to further reduce radiation exposure to both the surgeon and the patient.⁵⁴

Some authors have reported on the steep learning curve involved in transitioning from open to minimally invasive approaches.^{51,55} At present, there is scarce literature describing methods to improve learning efficiency and reduce the initial technique-related complications. Most surgeons would agree that with increased experience with minimally invasive techniques factors such as surgical times, blood loss, and complication rates are reduced as compared to those performed during the initial learning phase.^{51,55}

These issues can be taken in stride if the benefits of minimally invasive techniques truly outweigh the risks and translate into better clinical outcomes for patients. However whether these techniques significantly impact patient-related outcomes is still a matter of debate.

Patient Selection

In addition to the steep learning curve with MISS techniques there are a number of factors to consider in order to achieve optimal results.

Obesity

Minimally invasive spine surgery procedures are hypothesized to be advantageous in obese patients due to limited subcutaneous dissection and accelerated postoperative wound healing. However, excessively obese patients pose certain technical challenges. The distance from the skin to the intervertebral disc is greater which necessitates the use of longer instruments. A longer tubular retractor limits the degree of instrument angulation (*see* Fig. 132.9). This may

limit surgical access to the far reaches of the operative field and require excessive maneuvering of the retractor intraoperatively. Preoperative imaging studies must be analyzed in detail with obese patients to anticipate the length of the tubular retractor assembly required to perform adequate disc removal and decompression. In cases where this is unlikely to be fulfilled through MISS, open procedures should be considered.

Revision Surgery

Scar tissue from previous spinal surgery greatly increases the difficulty of reoperation. Wider surgical exposures are preferred for optimal appreciation of anatomy before approaching the scarred area overlying the dural sac. Complications such as dural tears occur more frequently during revision spine surgery.⁵⁶ In the event of a dural tear, open approaches offer distinct advantages in achieving effective repair compared to MISS. The surgeon should also be prepared to convert to open in cases where the technical difficulties and risks of complications outweigh the potential benefits of MISS. Considerable experience is required on the part of the surgeon to perform minimally invasive revision surgery safely and effectively in these complex cases.

Levels of the Involved Spinal Pathology

Smaller, localized spine pathology such as single-level disc herniation or canal stenosis is ideal surgical candidates for minimally invasive tubular surgery. The greater the number of spinal levels involved, the more difficult it becomes to adhere to minimally invasive practices. Multi-level herniations and extensive canal stenosis requiring bilateral decompression are more suited for open surgery. Additional steps, such as fusion and instrumentation, are often required in cases where adequate decompression may lead to spinal segmental instability. The complexity of surgery increases with the number of spinal levels involved.

Patient Education and Participation

It is important to discuss with patients the advantages and limitations of minimally invasive surgery so they are able to participate in the decision-making process. Patients should be well-informed before surgery of the difficult scenarios requiring conversion to open surgery for successful outcomes. This should not be viewed as a failure of the procedure or as a shortcoming of the surgeon. Rather it should reflect the judiciousness and ability of the surgeon

to instinctively adapt in the best interest of the patient. Finally, it must be emphasized that a good surgical candidate has a high chance of successful clinical outcome regardless of surgical approach.⁴⁵

Outcomes

The MSD described by Caspar⁵⁷ in 1977 has long been regarded as the gold standard approach for lumbar discectomies. Newer procedures are often evaluated in terms of efficacy, safety and outcomes in relation to this established technique. The current literature on MED suggests comparable short and intermediate term outcomes compared to both open surgery and MSD.^{52,58-60} Reported advantages of MISS procedures include less blood loss, smaller incision sizes, reduced length of hospital stays and decreased postoperative pain. Whether this translates into superior clinical outcomes has not yet been conclusively proven. Very few long-term follow-up studies are currently available evaluating the efficacy of these procedures. In a recent 10-year comparative study, Lee et al.⁶¹ observed no statistically significant differences between MED and MSD in terms of clinical and radiological outcomes, beyond an initial 3-month postoperative period. Other studies also failed to demonstrate any significant advantage for minimally invasive discectomy and decompressive procedures.^{62,63} More well-designed studies are needed before a definitive conclusion can be made regarding differences in outcomes.

In conclusion, minimally invasive microendoscopic techniques are safe and effective and comparable to standard open techniques in terms of patient-based outcome measures. Proper patient selection remains a crucial factor in achieving successful outcomes and minimizing complications using these techniques.

KEY POINTS

- The philosophy of MISS revolves around minimizing tissue trauma and the preservation of paraspinal muscle function and posterior spinal osseoligamentous integrity.
- Various minimally invasive approaches and techniques to the lumbar spine have been described and are used in practice. MISS using tubular retractor systems are based on the posterior interlaminar/translaminar approach.
- The indications for tubular retractor-assisted MISS for lumbar surgery have expanded greatly in recent

years, from simple discectomy to multilevel decompression and interbody fusion procedures.

- Patient selection is one of the most important factors in terms of optimizing results and reducing procedure-related complications.
- The techniques, at present, are relatively safe and afford comparable efficacy to the traditional open approaches. However, superiority over open surgeries in terms of clinical outcomes is currently unproven.

Minimally Invasive Transforaminal Lumbar Interbody Fusion

- » Outcomes

While the end of the last century may be deemed, “The age of the fusion cage”, the beginning of the new one has focused on a less traumatic delivery system for fusion hardware. Certainly lessons learned from studying results of open fusion surgery have shown complications compromising outcomes. Iatrogenic muscle injury leads to considerable postoperative pain and prolonged disability often with lengthy hospital stay.¹⁻⁴ Traditional open procedures are associated with significant blood loss often requiring transfusion.^{5,6} The accompanying soft tissue trauma is likely associated with adjacent segment disease.⁷

The above-mentioned problems associated with open surgery to fuse lumbar vertebrae have lead to ongoing exploration of less traumatic minimally invasive techniques. The hypothesized advantages of such approaches include: less blood loss, less postoperative pain; shorter hospital stay and faster time to narcotic independence.^{8,9} By definition these approaches are designed to preserve postoperative muscle volume.

With each attempt to minimize the trauma related to the surgical approach for delivery of interbody fusion cages, a new list of problems seem to arise. Posterior lumbar fusion, for example, increased fusion rates over posterolateral fusion, but at the expense of increased risk of neurologic injury. Transforaminal fusion again may decrease the incidence of neural injury compared to posterior lumbar interbody fusion, but at the risk of

iatrogenic instability. Still, as with all posterior approaches neural injury remains a concern.¹⁰

The concept of indirect neural decompression with anterior fusion is not new. Such procedures are designed to increase spinal canal volume and neuroforaminal surface area without risk of injury to the neural structures within the canal.^{11,12} None the less, anterior lumbar fusion does pose a risk for vascular injury as well as sexual dysfunction.^{11,13} Anterior fusion procedures achieve restoration of lordosis and disc height. A wide access to the disc space for thorough discectomy and end plate preparation provides ample space for large cages to increase fusion rates. This leads to their continued use.

Lateral lumbar interbody fusion techniques offer many of the advantages of anterior interbody fusion such as ability to restore lordosis and disc height, and insert large cages, but do so with less risk to the great vessels. There is also less risk to the sympathetic neural structures making the complication of retrograde ejaculation unlikely. These approaches have limited utility addressing pathology at L1-L2 and L5-S1. The approach itself, however, puts the lumbar plexus at risk for injury. Femoral nerve injury, thigh weakness, meralgia paraesthetica from genitofemoral nerve injury, quad and hip flexor weakness are but some of the reported complications just from traversing the psoas muscle.¹⁴ The standard risks of fusion surgery such as nonunion, subsidence, implant migration remain. Clearly approaching the intervertebral area for fusion preparation has some inherent risk.

Fig. 133.1: Kambin's Triangle: Boundaries are the superior articular process, the exiting nerve root and the vertebral body below.

Fig. 133.3: Surgical access corridor: Demonstrates muscle preserving approach between iliocostalis and quadratus lumborum.

In attempt to find a safer access to the disc space, we have been utilizing Kambin's triangle. This space is bound by the superior articular process posteriorly and the superior end plate of the vertebral body below. The roof or hypotenuse of the triangle is the exiting nerve root. the dimension of the space average 12.3 mm in height. The hypotenuse is 23 mm long, and the inferior border is 18.9 mm on average. In assessing feasibility for passage of instrumentation, cannulas up to 10 mm can safely pass into this space¹⁵ (Fig. 133.1).

Although this represents a new fusion access corridor, Kambin's triangle has been shown as a safe path for

Fig. 133.2: Neuroforamen and exiting nerve root directly decompressed for procedure.

discectomy since the 1970s. Whether performed through cannulas,¹⁶ automated suction devices,¹⁷ or with lasers for disc decompression¹⁸ tens of thousands of these cases have been performed with complication rates lower than 1%. Advances in endoscopic visualization and instrumentation have expanded the indications for these procedures to include removal of extruded migrated herniation fragments, and to relieve stenosis by bone removal with endoscopic burr systems (Fig. 133.2).

This access to the disc space is the least traumatic to the musculature. It utilizes the natural plane between the iliocostalis and quadratus lumborum muscles. Complete discectomy and endplate preparation are accomplished through an 8 mm cannula (Fig. 133.3).

TECHNIQUE

To accomplish discectomy and cage insertion safely through Kambin's triangle, care must be taken to identify the appropriate skin origination point for cannula insertion. It is also imperative to have all instruments parallel the inclination of the disc space so as to not violate the vertebral body endplates and risk cage subsidence. The skin window to the disc is established by a modification of the technique described by Yeung. With the patient appropriately positioned on a frame in the prone position the disc center is marked on the skin in the horizontal and longitudinal axis (Figs. 133.4A and B). Next, in a true lateral projection, the disc inclination is marked on the patient's side (Fig. 133.5). This inclination must be parallel to the disc space. Instruments are inderted along the path marked by the

Figs 133.4A and B: Disc center determined on AP fluoroscopy.

Fig. 133.5: Disc inclination determined with true lateral image.

Fig. 133.6: Skin window for disc access: The initial start point intersects the inclination line of the disc. The distance off the midline is the distance from dorsal skin to the disc center at L3-L4 measured from lateral inclination X-ray. For L4-L5 and L5-S1, the distance is from dorsal skin to junction of anterior and middle one-third of disc.

inclination line. As such, entry to the disc spaces at L5-S1 and L4-L5 typically is cephalad to the disc target, and L12 and L2-L3 disc spaces are usually targeted from a more caudal starting point. The distance from the midline to make our skin incision is also determined by lateral fluoroscopic image and is the distance from the dorsal skin to the junction of the middle and anterior third of the disc at L4-L5 and L5-S1. For L1-L2 and L2-L3, our starting point is closer to midline, the distance from dorsal skin to the junction of the anterior and middle third of the disc. It is important to note that the skin window is not necessarily in line with the disc location, but rather is the distance off center that intersects our inclination line (Fig. 133.6).

As this technique is the most tissue sparing way to reach the intervertebral space muscle preservation is considered at each step. Prior to skin incision, the authors recommend inserting a spinal needle through Kambin's triangle. This helps to confirm our inclination of approach parallels the disc space and that our trajectory will allow crossing the midline of the disc as close to 45° as possible to allow symmetric restoration of disc height. Once confirmed, a 12–15 mm skin incision is made. We prefer to penetrate the lumbar fascia with a blunt dilator to minimize bleeding and muscle trauma.

The protocol for this procedure calls for a blunt tip electromyography (EMG) probe to be used as the initial instrument to pass through the working safe zone. Once on the disc the probe is stimulated. The minimum threshold of safe distance from the exiting nerve root is a lack of neurologic response from a 3 milliamp stimulus. This confirms at least a 1.5 mm space between the exiting nerve root and the probe. Usually higher thresholds are obtained implying greater distance from the neural structures. If a neurologic response is elicited by low stimulus, the probe should be backed out of Kambin's triangle and repositioned. It is critical to not proceed with this procedure if safe passage past the nerve is not demonstrated. Should this situation arise, two options are available: conversion to traditional TLIF, or foraminal decompression. One of the authors, has reported previously on endoscopic foraminal decompression to increase the space available for instrument passage past the exiting nerve root.¹⁹ This technique requires specialized endoscopic equipment not routinely used for Kambin's triangle fusion surgery. It has been demonstrated to provide

safe access to the disc space and lessen dysesthesia incidence (Fig. 133.7).

After safe access to the disc space is confirmed, a sheath is advanced over the EMG probe and anchored on the disc and a guidewire is placed through this into the disc space. At this time the trajectory of the instrumentation is confirmed with AP and lateral fluoroscopic images. The guidewire should ideally be in the disc center on both images to assure as close to a 45° angle path across the disc. If this is not the case, raising or lowering the hand allows adjustment of the trajectory.

Once the guidewire is safely inside the disc, blunt dilators are used to divide the lumbar musculature. The

tubular access working cannula is then anchored in the disc space over the dilator using a mallet. Ideal position is confirmed with fluoroscopy when the cannula is at the medial border of the pedicle on AP image and about 25–30% into the back of the disc on lateral image. This roughly coincides with the annular nuclear junction.

From this point, all disc decompression and endplate preparation is accomplished through this 8–9 mm outer diameter tube. Options exist depending on device used to do disc work using expanding disc shapers and loop curettes through the tube with pituitary rongeurs to remove debris, or to do disc work endoscopically. The endoscope does allow for removal of extruded and migrated fragments as part of procedure (Figs. 133.8A to D).

Once endplate preparation has been accomplished, bone grafting is done through filler tubes through our access cannula to restore disc height and provide anterior column support. If desired trial prostheses may be placed before grafting, however as the expansile discectomy instrument increases its size in 1 mm increments, most surgeons use this device to determine implant size. By doing so, fewer passes of instruments past the exiting nerve root are done, so less nerve root retraction is required.

The fusion implants presently available do not pass through the working cannula. As such, after bone grafting, the blunt guidewire is again placed into the disc space. By placing the wire through the initial blunt dilator we assure central position of the guidewire. Care is then taken to remove the dilator and working cannula without displacing the guidewire.

Fig. 133.7: Foraminal decompression: endoscopic images of foraminotomy.

Figs. 133.8A to D: Expanded indications for the technique: Use of endoscope allows additional decompression within the canal and offers opportunity for direct and indirect decompression.

Figs. 133.9A and B: Cage subsidence: Early and late postoperative X-rays demonstrate cage subsidence.

Implant insertion is next done. The implant is passed over the wire through Kambin's triangle until it is against the disc. Care must be taken to avoid guidewire advancement by bending the wire over the inserter handle. Before final insertion, make sure the implant is correctly rotated to its final resting position. The cage can then be advanced into the disc space. The bullet tip of the implant will retract the exiting nerve root like the initial dilator and will gradually restore disc height. Final position should show the implant centered on the spinous process in the AP fluoroscopic image, and centered in the disc space laterally.

These fusion procedures are not stand alone implants and should be augmented with posterior fixation. Both authors use bilateral pedicle screw fixation with compression for additional fixation.

COMPLICATIONS

As is the case with all emerging technology, complications do arise. Fortunately, due to the proven safety of the Kambin's triangle approach, no serious adverse effects have been reported. There have not been any bowel or visceral injuries, nor have there been any vascular complications. This technique does not put the lumbar plexus at risk. Dural tears or epidural scarring has not occurred. Dysaesthesia remains the most common complication and occurs in 30% of cases. It is almost always transient, but if poorly tolerated by patients can be lessened with transforaminal nerve blocks and gabapentin. Advising patients preoperatively of potential new or increasing leg pain for a period of time post operatively makes these complaints minor.

Nonunion remains an unanswered dilemma in 10% of cases. Perhaps better bone graft substitutes may lessen the incidence.

Cage subsidence is also seen in 15% of cases (Figs. 133.9A and B). Care in avoiding violation of the end plate during preparation lessens the incidence of this, as does implant insertion parallel to disc space. Expanding and lordotic implants are being evaluated to see if this may decrease the frequency of this adverse outcome. It is important to not oversize the implant, as this may lead to endplate failure, which again is associated with cage subsidence. Ultimately, the dimensions of Kambin's triangle limit implant size and fusion footprint, as such, in cases of very portic bone alternative techniques should be considered.

Hypesthesia lasting longer than three months is seen in 10% of cases. Typically this is seen as slight diminution of sensation in the L5 nerve root distribution after L5-S1 surgery particularly in cases with a high iliac crest or narrow foramen.

Implant failure or fracture of a 2 mm corner of an implant occurred in one case while attempting to distract a very collapsed L5-S1 disc space. The small fractured fragment was easily removed not affecting the implant integrity. As a caveat, make sure inserter is firmly attached to implant, as the fracture occurred at the screw thread junction.

Motor weakness lasting longer than three months is not common. We have only had 2% of cases with residual weakness of the extensor hallucis muscle after L5-S1 fusion.

Blood loss averages 50 cc or less for these procedures. No patient has needed a transfusion.

Infection is rare as the access corridor leaves no dead space. We have had no early and only one delayed infection in a non-controlled diabetic with blood sugars over 500.

Implant migration has occurred in one case of nonunion. This implant was removed by screwing the threaded part of the inserter into the cage through the original incision. The implant can then be retrieved. The procedure was then revised through the original technique achieving fusion.

OUTCOMES

We have successfully performed this procedure in 100 patients addressing pathology from L1-L2 to L5-S1. Visual analog score (VAS) back and leg improved by greater than 5 grades. All procedures are done in outpatient or overnight setting. About 90% of patients would undergo the procedure again or recommend it to a friend. Return to work is typically in three to six weeks depending on job summary. Narcotic independence is three weeks or less.

SUMMARY

Kambin's triangle allows reliable safe access to the disc space for decompression and interbody cage insertion. While minor complications do arise, serious ones are avoided. Due to the limitations of existing hardware, nonunion and cage subsidence do still occur.

CONTEXT

Modern medicine and technology have created an unprecedented level of care, comfort, and convenience for citizens of developed nations. Concomitantly, the percentage of elderly patients has increased significantly. In 1990, there were 37,306 Americans Centenarians, but it is estimated that by 2050 there will be 4.2 million persons aged 100 or older (Fig. 134.1).¹ These changes will impact providers of spinal care significantly, as degeneration of the spinal column is associated with increasing age. Data from the

Fig. 134.1: Number of US centenarians.

National Health and Nutrition Examination Survey (NHANES) study estimates the prevalence rate of scoliosis at 8.3% in adults (defined as $>10^\circ$ curves).² More importantly, the prevalence and severity of spinal deformities increase with age and loss of bone mineral density. Thus, spinal surgeons will be increasingly caring for elderly patients with adult spinal deformity (ASD).

Adult spinal deformity remains a challenging proposition for the spinal surgeon. A combination of factors results in high intra- and postoperative complication rates with the surgical correction of ASD. These factors include an increased number of medical comorbidities, patient deconditioning due to pain and immobility, associated osteoporosis, a rigid skeletal deformity, and abnormal spinal anatomy.^{3,4} In addition, the surgical intervention necessary to treat these patients is typically a long-segment fusion with fixation and osteotomies, often in concert with interbody fusion or anterior access. This results in a painful, debilitating operation that requires prolonged anesthesia, long recoveries, and extended hospital stays. Thus, it is not surprising that reports from expert deformity surgeons reveal a high rate of serious complications. For example, in Kostuik's series of 361 patients, the 30-day mortality rate was 2.4%.⁵ A recent report by Smith et al. analyzed data from the Spinal Deformity Study Group showing that 26.2% of their 206 patients suffered a minor complication, and 15.5% suffered a major complication.⁶

Minimally invasive surgery (MIS) alternatives were developed over the past decade in an attempt to manage these patients with lower surgical morbidity rates.⁷⁻⁹ The degree to which this has been successful to date is a matter of considerable debate. However, the laudable goals of reduced blood loss, lower narcotic consumption, faster mobilization, and reduced infection rates have been effectively demonstrated in short segment MIS spine surgeries, such as MIS transforaminal lumbar interbody fusion (TLIF) when compared to traditional open operations. If these effects can be translated to the ASD population, MIS techniques would represent a significant advance.

A variety of techniques have been developed in an attempt to apply MIS methodologies to correct coronal and sagittal deformities. This chapter will outline three different categories of techniques, each with potential advantages and drawbacks. It should be understood that subtle differences in technique exist between surgeons and centers, and these nuances can be critical to successful patient outcomes.

LATERAL INTERBODY FUSION WITH PERCUTANEOUS SCREWS

One of the more popular minimally invasive techniques for treating ASD is a lateral interbody fusion at multiple lumbar levels followed by percutaneous screw placement. This method was popularized following the introduction of a method innovated by Pimenta for accessing the disc through a direct lateral trajectory.¹⁰ This was similar to open lateral interbody fusion through a thoracoabdominal approach in that the spine was accessed through the retroperitoneal space, which had already been effectively used for years to access the L1-L5 disc spaces. However, the advent of tubular dilator retractors and the development of continuous running electromyography allowed the surgeon to use only a small incision and to access the intervertebral disc through the muscle belly of the psoas. Safe navigation around the lumbar plexus was critical to this technique.

With the patient in lateral position, multiple disc spaces could be accessed and treated with significant improvement in coronal alignment and scoliosis. While stand-alone constructs have been used, most significant deformities are treated with supplemental fixation, which was now possible with the use of percutaneous pedicle screw-rod constructs (Figs. 134.2A to F). Detailed descriptions of the nuances of this method can be found in other chapters of this textbook. This technique has been applied with much

enthusiasm and has proven excellent for treating local degenerative arthritis, restoring foraminal height, achieving indirect neural decompression, and correcting coronal deformity.^{7,9,11-13} In addition, the results with these surgeries in the published literature have generally been associated with reductions in total blood loss and almost no cases of wound infection.

However, four significant drawbacks remain with this approach. First, the need for lateral as well as prone positioning prolongs anesthetic time in this medically compromised patient population, as two-position surgery (supine then prone) has traditionally been very time-consuming. Some surgeons have attempted to circumvent this problem by performing percutaneous screws, while the patient is in the lateral position. This can be technically more challenging for fluoroscopic imaging and is more efficient with the use of frameless navigation. Others object to the non-ergonomic work posture for the surgeon. A second solution has been to stage these surgeries. Following the direct lateral operation the patient is allowed to convalesce, and this will allow the surgeon to ascertain whether any indirect neural decompression has been effective. This allows the second prone surgery to be accompanied by a direct neural decompression (laminectomy or foraminotomy) if needed. This approach, of course, adds significant cost and subjects the patient to two anesthetic episodes.

The second major drawback has been the relative inability to treat the lumbosacral junction from the lateral approach. Surgeons desiring to fuse this area have in the past combined the procedure with an MIS TLIF or transsacral interbody screw. Others have opted to even take the extreme measure of drilling through the iliac crest to access L5/S1. Regardless, it is clear that access to the more caudal spinal levels results in higher rates of inadvertent injury to the lumbosacral plexus, even with the use of neuro-monitoring.^{14,15}

In addition, the inability to treat the lumbosacral junction can be a critical downfall if the patient has a significant fractional curve. This curve, at the base of the spine, can set the plane of the midlumbar spine at an angulation. Subsequent correction or straightening of the midlumbar curve (which is usually the more obvious or larger curve) can throw a previously coronally aligned patient out of balance. Lack of care and attention to spinal balance and the fractional curve can thus result in worsening of spinal alignment after surgery.

The third drawback of this approach has been that it is unproven for correcting severe, stiff curves of $>50^\circ$.

Figs. 134.2A to F: Case example of using direct lateral interbody fusion technique for treating adult scoliosis. (A) The patient's single photon emission computed tomography bone scan shows back pain emanating primarily from arthritic changes in the upper lumbar spine. (B) Positioning in the operating room allows for a lateral jack knife position that opens the concavity of the curve. (C to F) Pre- and postoperative X-rays showing a T11-L4 minimally invasive surgery instrumented fusion with lateral interbody cages at L1–L4. Facet fusion is performed at T11-L1.

In series reported to date, the majority of curves have had a Cobb's angle of $<30^\circ$. In Uribe's series of 25 patients only four patients had a scoliosis of $>30^\circ$.¹² In Anand's series of 28 patients, Cobb's angles ranged from 15° to 62° , but averaged only 22.3° .¹¹ In Kanter's series of eight patients, the curves were more severe. Preoperative Cobb's angles ranged from 18° to 80° and averaged 38.5° . However, this series utilized an open second posterior approach, allowing for posterior column osteotomies and open screw-rod manipulation techniques to assist with curve correction.¹⁶ Advances in the application of lateral release and cage insertion techniques will likely result in the ability to treat greater curvatures, as this landscape is still evolving.

Finally, this approach has resulted in only minimal or modest improvements in lumbar lordosis. In the recent series of 35 patients by Acosta et al., the lateral MIS approach allowed for a Cobb's angle correction from 21.4° to 9.7° , a statistically significant improvement.¹⁷ However, lumbar lordosis only changed from 42.1° to 46.2° despite improvements in interbody height. Overall, the global sagittal alignment was unchanged. This is similar to the finding of a 5° improvement in global lordosis published by Karikari et al.¹⁸ Given the importance of maintaining or improving sagittal parameters in the ASD patient population, this represents an important deficit in this particular MIS technique for addressing ASD.

MULTILEVEL MINIMALLY INVASIVE SURGERY TRANSFORAMINAL LUMBAR INTERBODY FUSION

One- and two-level MIS TLIF has become very popular for treating spinal stenosis, disc reherniation, spondylolisthesis, and other degenerative spinal disorders. Part of the appeal of MIS TLIF has been that it allows for the complete treatment of a spinal segment, including neural decompression, interbody fusion, and stabilization. The recent literature has supported the notion that when compared with open TLIF, the MIS TLIF can generally be regarded as accomplishing the same goals of surgery, with attendant decreases in blood loss, infection rates, and hospital length of stay. Whether the clinical significance of these differences is meaningful can still be debated, but the effects are likely to be real.

Multilevel open TLIF has also been shown to be an effective strategy for managing less severe cases of spinal deformity. A previous clinical series by Scheufler et al. demonstrated the efficacy of multilevel MIS TLIF to obtain improved lordosis in the ASD population.⁸ In that series of 30 patients image guidance was used to plan and place hardware for interbody as well as transpedicular fixation. An excellent mean correction of 31.7° and 44.8° in the coronal and sagittal planes, respectively, was achieved. Thus, the use of TLIF for deformity surgery as described by Heary and Karimi¹⁹ appears to afford the opportunity for improved deformity correction. This procedure at multiple levels has been improved with the use of modern expandable cages and percutaneous pedicle screws (Figs. 134.3A to E). One of the appeals of this approach has been that with a single position surgery, the complete operation can theoretically be accomplished in a reasonable timeframe, limiting the anesthetic risks to the patient.

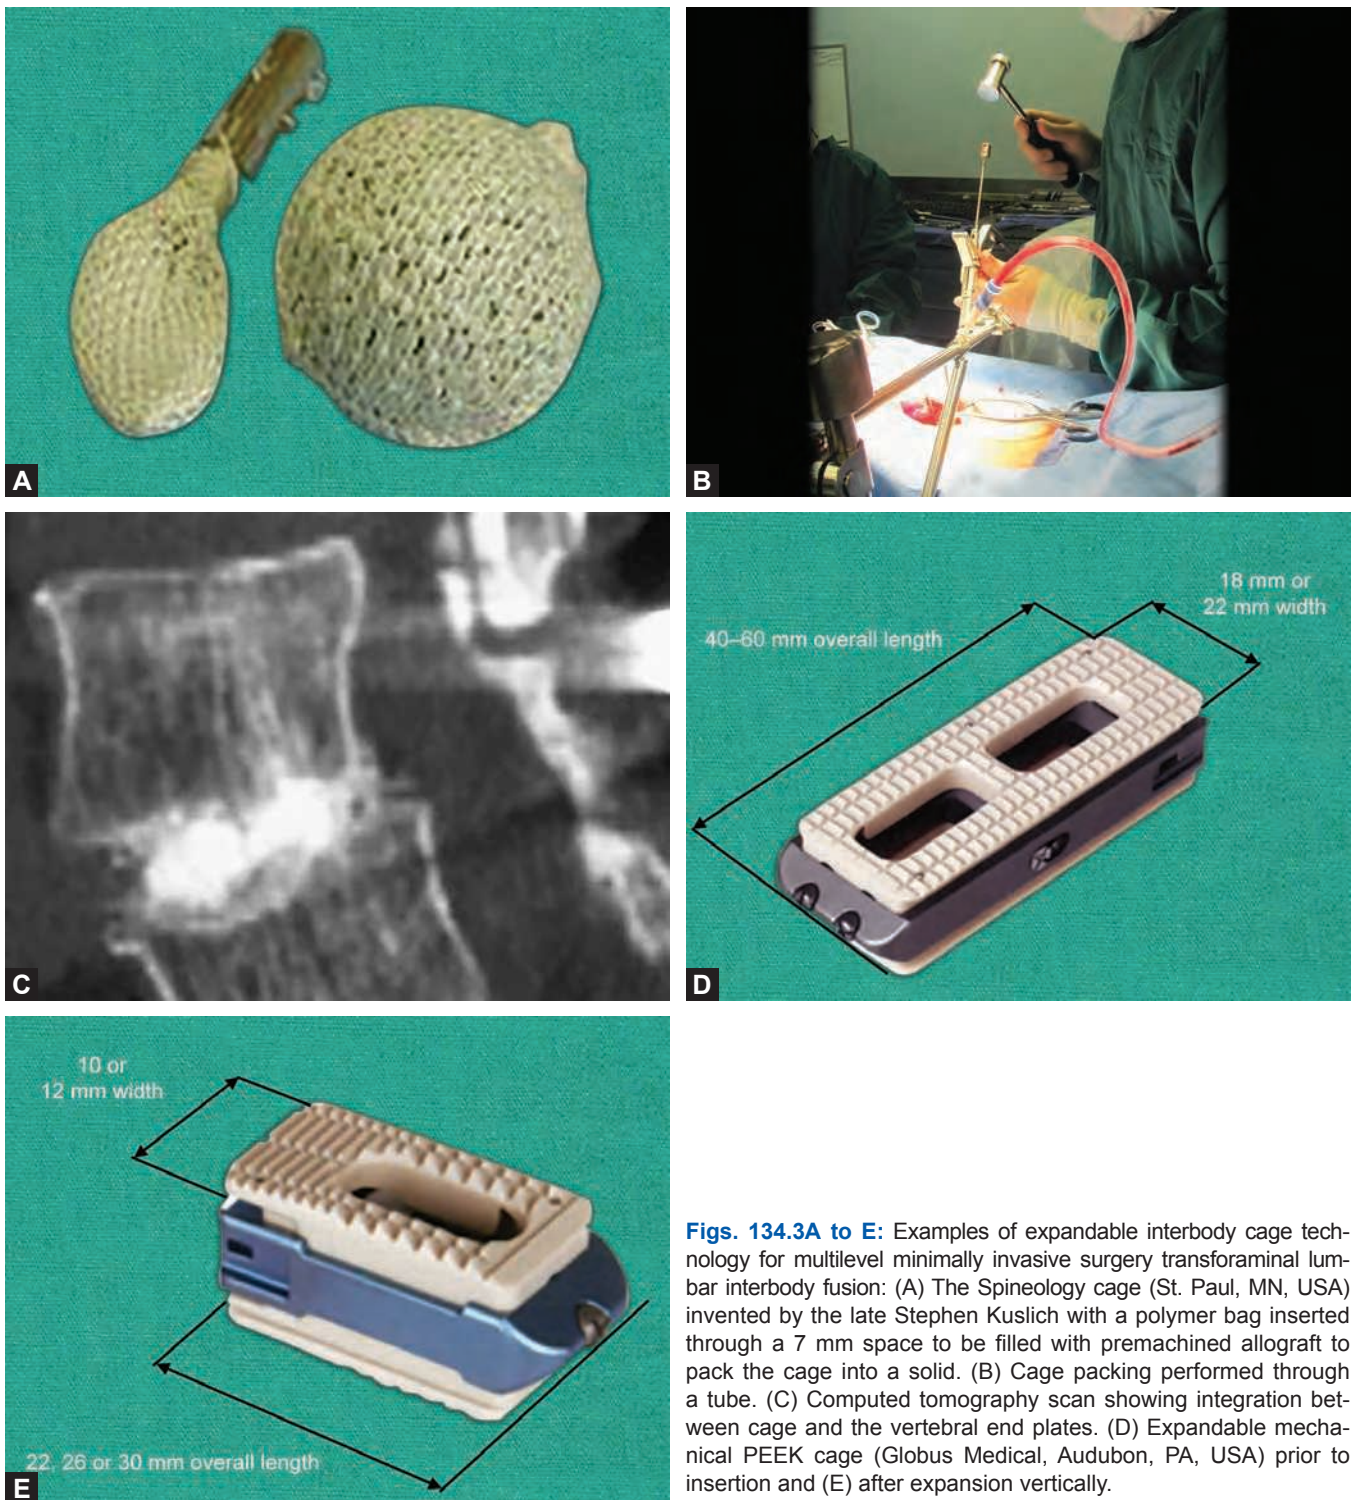

Surgical Technique

The surgery is accomplished in the prone position under general anesthesia. Positioning on the Jackson table is critical to allow the belly to hang and increase lordosis after the releasing osteotomies and disc removal. A single midline incision is made over the segments to be treated. This technique prevents the creation of undue cosmetic defects, problems often seen with multiple stab incisions. A plane is created above the superficial fascia so that percutaneous screws can be placed with minimal disruption of the soft tissue envelope. Only one side of the spine is accessed to allow for facetectomies and interbody cage placement. A subperiosteal dissection is then taken to the lateral facet

joints only on the side of approach for the MIS TLIFs, and the contralateral side is not exposed below the fascia. The choice of which side to approach from will depend on the type of deformity, clinical symptoms, and the goals of surgery. Typically, approach is made from the concavity of the fractional curve (the curve at the lumbosacral junction) which is the same side as the convexity of the major curve (which is typically midlumbar).

Following exposure and confirmation of spinal levels the facet osteotomies are performed from lateral to medial across the superior facet just rostral to the pedicle. A cerebellar retractor is used to elevate the soft-tissue envelope. A midline laminectomy is not typically performed unless there is severe central canal stenosis that requires direct decompression. An osteotomy is performed at each MIS TLIF level. The operating microscope is then used to more clearly visualize the critical structures. Bone, joint, and soft tissue removal is then taken medially up to the lateral border of the ligamentum flavum at a minimum. The lateral annulus is then found just rostral to the pedicle and the surrounding veins are coagulated using bipolar cautery. An incision is made through the annulus and insert-and-rotate shaver dilators are used to remove the intervertebral disc, with great care taken to preserve the cortical vertebral end plates. This is particularly important in the setting of osteoporosis. In addition, the medial angulation of the approach is critical and will differ by level. In surgeries where the approach is on the side of the concavity (simple curves without a fractional component) the disc removal will be predominantly ipsilateral in order to distract the interspace that has been closed down. In surgeries where the approach is on the side of the convexity of the major curve (this is also the side of the concavity of the fractional curve), the contralateral side of the disc is accessed and removed so that interspace height can be restored on the collapsed portion of the major curve.

Once complete disc removal has been accomplished, fusion adjuvants are placed into the disc space. Autograft bone from the facetectomies is used, as well as rh-BMP-2 (InFuse, Medtronic Sofamor Danek, Memphis, TN, USA) at a dose of up to 1.05 mg/level. A 25 mm Optimesh (Spineology, Minneapolis, MN, USA) cage may be inserted and internally filled with allograft granular matrix. The device is inserted through a 7-mm diameter portal and inflated within the disc space, restoring intervertebral height. It should be noted that both of these products used in this setting are considered “off label” by the Food and Drug Administration. Once filled and inflated, the cages are crimped shut and the nerve roots are inspected to ensure there is no impingement.

Figs. 134.3A to E: Examples of expandable interbody cage technology for multilevel minimally invasive surgery transforaminal lumbar interbody fusion: (A) The Spineology cage (St. Paul, MN, USA) invented by the late Stephen Kuslich with a polymer bag inserted through a 7 mm space to be filled with premachined allograft to pack the cage into a solid. (B) Cage packing performed through a tube. (C) Computed tomography scan showing integration between cage and the vertebral end plates. (D) Expandable mechanical PEEK cage (Globus Medical, Audubon, PA, USA) prior to insertion and (E) after expansion vertically.

Percutaneous screws are then placed by cannulating the pedicles using Jamshidi needles. This is accomplished primarily using anteroposterior (AP) fluoroscopic

X-rays. The technique involves docking the needle tip at the junction of the transverse process and lateral facet joint. The needle is malleted into the bone 2 cm without

Figs. 134.4A to D: (A and B) Preoperative and (C and D) postoperative 36-in standing radiograph for a mini-open T10 to L5 surgery with expandable cages and MIS TLIF at L1–L5.

passing the medial wall of the pedicle on AP X-ray images. This use of the AP technique allows accurate compensation for axial rotation in complex ASD cases. Iliac screws are placed using the obturator outlet view for percutaneous cannulation as previously described.²⁰ For iliac screws, a window is made in the posterior superior iliac spine to avoid screw head prominence. Each needle is then exchanged for a Kirschner wire. An insulating sheath protects the soft tissues, while an awl and tap create the path for the pedicle screw, followed by final screw placement (Viper, Depuy Spine, Raynham, MA, USA).

Rods are placed subfascially by passage through the screw extensions. For the levels fused without an interbody cage, a posterolateral fusion is performed. This is accomplished by decorticating the lamina and facet joint through the same fascial incision used for screw placement. Autograft bone and remaining rh-BMP-2 are used to fuse these levels at the thoracolumbar junction. Rod derotation, compression of screw heads along the major curve convexity, and persuasion of the rod to the screw heads are then used to complete the deformity correction. The surgical sites are then closed in standard fashion over suction drainage.

Initial Clinical and Radiographic Results

In a recent clinical series of 25 patients from our institution, patients with curves of 20° or greater were effectively treated. The mean age was 72 years (range of 62–84). Seventeen were women and 8 were men. The mean height and weight were 163.2 cm and 74.3 kg, respectively, with an overall average BMI of 27.8 (range of 21.3–43.5). The

mean weighted Charlson comorbidity score was 1.0 and the combined Charlson score mean was 3.8. A total of 132 segmental levels were treated (mean = 5.28), and 80 interbody levels were treated (mean = 3.2). A total of 256 percutaneous pedicle screws and 14 percutaneous iliac screws were placed. The series was consecutive with no patients lost to follow-up. All surgeries were successfully completed without conversion to an open operation with an average operative time from skin incision to final closure of 273 minutes (range of 180–360). The surgical blood loss as measured by the perfusionist averaged 415.6 mL (range of 200–800 mL). Ninety-two percent of patients were out of bed and ambulating on the first postoperative day, with a mean acute care stay of 5 days (range of 3–8). Eighty percent of patients were discharged home, and 20% were sent to inpatient rehabilitation.

Radiographic outcomes were determined using pre- and postoperative 36" standing X-rays at last follow-up (Figs. 134.4A to D), which was at the 12-month time point. The mean preoperative Cobb's angle was 29.2° + 9.3 (range of 20°–59°). This improved to a mean of 9.0° + 5.0 (range of 3°–21°). This reflected an average of 20.2° of improvement and was a statistically significant improvement ($P < 0.001$). The mean preoperative global lumbar lordosis was 27.8° + 12.9 (range of 6°–53°). This improved to a mean of 42.6° + 12.1 (range of 19°–66°). This reflected an average of 14.78° of improvement and was also a statistically significant improvement ($P < 0.001$). The mean preoperative sagittal vertical axis (SVA) was 7.4 cm + 4.9 (range of 0–17.5 cm). This improved to a mean of 4.3 cm + 5.7 (range of 0–13.0 cm). This reflected an average of

Figs. 134.5A to D: (A and B) Preoperative and (C and D) postoperative 36-in standing radiograph for a mini-open T11 to Iliac surgery with expandable cages and MIS TLIF at L2-S1.

3.2 cm of improvement and was a statistically significant improvement ($P = 0.001$). Fourteen patients had at least 1 cm of coronal imbalance before surgery (range of 0–5 cm). Preoperative mean coronal imbalance was 1.64 cm, improving to 0.72 cm, reflecting a mean improvement of 0.92 cm. Three patients had a worsening of coronal balance due to straightening of the major curve without addressing the fractional curve adequately. Two of these patients worsened from 1 to 3 cm, and one patient worsened from 2 to 3 cm (Figs. 134.5A to D).

Clinical outcomes were ascertained using the numeric pain score (NPS) for the lower extremity (leg and buttock symptoms) and lower back (axial symptoms) on a scale of 1–10 (10 being highest) as well as the Oswestry Disability Index (ODI). Questionnaires were completed in the clinic setting before surgery and afterward at 12-month follow-up. Preoperatively, the NPS for leg pain was 5.1, improving to 1.8 after surgery, reflecting a mean improvement of 3.3. Preoperatively, the NPS for axial back pain was 7.6, improving to 3.4 after surgery, reflecting a mean improvement of 4.2. Preoperatively, the ODI was 44.9, improving to 24.1 after surgery, reflecting a mean improvement of 20.8. There were no cases of neurological worsening except for one patient with new foot dorsiflexor weakness. Of the 16 patients with preoperative nerve root pain, all but one had resolution of leg pain. A total of six complications occurred. Four were hardware-related complications. Two patients had a medial L5 screw breach. In one case, this was removed 2 weeks after the index surgery due to foot weakness. In the other case, the patient only had

numbness and the screw was removed after confirmation of solid bony fusion 9 months after surgery. One patient had an asymptomatic grade II T10 screw breach. One patient had early pullout of one S1 screw that was removed 1 year later after confirmation of successful fusion at L5/S1. Thus, a total of three patients had a return to the operating room during the follow-up period, one of which was acute and two of which were delayed. The fifth complication was a case of acute coronary syndrome occurring in a 79 female who did not suffer from permanent myocardial ischemia. The final complication was a patient with prolonged hospitalization due to severe constipation. This patient was ultimately discharged home.

MINI-OPEN PEDICLE SUBTRACTION OSTEOTOMY

Given the importance of sagittal balance for good clinical outcomes, more powerful methods for improving spinal alignment have been needed. One of the most versatile and powerful techniques for improving sagittal balance is the pedicle subtraction osteotomy (PSO).²¹ Performed with open surgery, this method is associated with a high but unavoidable complication rate due to the significant blood loss, frequent history of previous surgery, advance age, and manipulation of critical neurovascular structures.

We have begun to develop a method for mini-open PSO. Because of the inherent danger of uncontrollable blood loss and neural injury at the osteotomy site, we have chosen to open this area selectively, but the approach limits destruction to the soft tissue envelope and blood loss.

SURGICAL TECHNIQUE

Following intubation, the patient is positioned on the Jackson table. A dorsal midline skin incision is made from the lower thoracic area to the sacrum. Subcutaneous dissection then allows the muscle fascia to be exposed so that all subsequent steps are performed through the fascia. This is preferable to using multiple stab incisions that are cosmetically unfavorable and result in more blood loss. A bilateral subperiosteal dissection is then achieved at the level of the intended PSO. The exposure is taken laterally to the transverse processes at target level. If an interbody fusion below the level of the PSO is desired, then a unilateral subperiosteal exposure of the facet joints is undertaken at those levels to allow for MIS TLIFs.

The target spinous process, lamina, and facets are then removed with a rongeur. The exiting nerve roots are fully exposed and the annulus of the disc above the target pedicle is cauterized with a bipolar and incised with 15-blade scalpel to create an extended PSO. The pedicles are then removed entirely using rongeurs and the high-speed drill. A bilateral decancellation osteotomy was then performed using a series of enlarging curettes to remove

two cones of cancellous bone from the vertebral body. Central bone is removed with a curved curette and the decancellation is extended superiorly into the disc space. Cottonoids are used to dissect and secure the lateral vertebral wall and its associated vasculature. A Leksell rongeur is used to remove the lateral vertebral body wall bilaterally in a wedge-shaped pattern to match the decancellation.

Control of the spine is then achieved by placing percutaneous pedicle screws at least three levels above and below the PSO site. An AP-based fluoroscopic technique is utilized to compensate for axial rotation of the vertebral bodies. The pedicle screw extensions are used to prevent any catastrophic vertebral translation during completion of the osteotomy. The posterior vertebral body wall and posterior longitudinal ligament are removed by retracting the thecal sac medially on each side successively.

After ensuring there is no ventral bone or ligament that might impinge on the thecal sac, the osteotomy is closed. A total of four rods are bent to the same degree of lordotic curvature (approximately 35°). Each rod is passed through each set of screw heads above and below the PSO (Figs. 134.6A to F). This is done as it is not possible to pass a lordotic

Figs. 134.6A to F: Case example of a mini-open pedicle subtraction osteotomy. Artist's depiction of mini-open PSO correction before (A) and after (B) osteotomy closure. (C to F) Pre- and postoperative anteroposterior and lateral 36-in standing radiograph.

rod below the fascia in a kyphotic region of the spine. A rod-to-rod connector is then placed on the end of each rod at the PSO site where the tip is exposed. Set screws are then used to loosely attach each of the four rods to its respective set of screws. By holding each of the four rod holders and forcing them toward each other the osteotomy site is greenstick fractured and the spine is placed into lordosis. At this point, the four rod-to-rod connectors are used to rigidly attach the cranial rod to the caudal rod on the same side. The set screws are fastened tightly and all articulations are then finally tightened.

The nerve roots and thecal sac are then inspected to ensure that there is no neural compression, and any bleeding is controlled with powdered collagen matrix. A small subperiosteal exposure is then achieved on one side at the top of the construct and an interlaminar fusion is created between the top three vertebral segments using autograft bone. The wound is then closed over suction drainage in standard fashion.

FUTURE DIRECTIONS

Significant gaps remain in the MIS spectrum of techniques for treating complex spinal problems in challenging patient populations. Future advances in the ability to mobilize the spine prior to realignment, decrease rates of pseudoarthrosis, safely place implants for fixation, and initiate powerful corrective maneuvers will be necessary to advance the field if an MIS approach is to achieve the results seen with powerful three-column osteotomies. However, improvements in spinal instrumentation, image guidance, and osteobiologics will likely make MIS ASD surgery a viable option for the increasingly aging patient population.

KEY POINTS

- The aging of the US population will result in an increasing need for surgeons to be able to manage ASD in the elderly.
- Several minimally invasive options are available currently for treating ASD, each with its specific benefits and drawbacks.
- Minimally invasive lateral interbody fusion is effective at correcting moderate scoliosis, but restoring sagittal balance has been more elusive.

- Mini-open multilevel TLIF is effective for efficient neural decompression and can yield correction of moderate deformities in both the sagittal and coronal planes.
- Mini-open PSO has promise for correcting cases with more severe sagittal imbalance.

Use of Navigation in Spine Surgery

- » Deformity Surgery

INTRODUCTION

Computer-assisted spine surgery describes a group of technologies that merges preoperative or intraoperative images with three-dimensional (3D) visualization of surgical instruments in real time. Computer-assisted navigation system was first introduced in clinical practice for transpedicular screw fixation in 1995.¹

The use of pedicle screw fixation has improved the mechanical rigidity of the constructs used for spinal stabilization and deformity correction. Pedicle screw fixation enables shorter fusion length and better correction, and achieves three-column fixation and higher rates of fusion. However, pedicle screw fixation is challenging because a significant portion of spinal anatomy is not visible and therefore instrumentation requires inference of spinal anatomy from surface landmarks. The difficulty is further pronounced in situations where the spine is deformed, the landmarks are obliterated and in revision spine surgery.

Traditionally, surgeons relied on their knowledge of anatomy of spine along with images acquired preoperatively and intraoperative fluoroscopy. Intraoperative fluoroscopy is commonly used to assist in localization of skin incision, identification of the proper anatomical level, and confirmation of correct positioning of spinal implants.² Intraoperative fluoroscopy delivers real-time images of the spinal anatomy, but in a single plane and the repeated use of C-arm during surgery results in significant radiation exposure both to patient and surgical staff. Also freehand

and fluoroscopy-guided pedicle screw placement can have misplacement rates up to 30% in the lumbar spine and up to 50% in the thoracic spine.³⁻⁵

In 1987, the Scoliosis Research Society reported an incidence of 3.2% of nerve damage after the use of pedicle screws,⁶ and West et al. in 1991 described a nerve damage rate of 2% associated with misplaced pedicle screws. Using intraoperative fluoroscopy, Castro et al.⁷ reported an incidence of 40% of misplaced screws. The suboptimal position of the screws also has an effect on the implant biomechanics and may lead to early failure. Also of concern is the medicolegal implication of the displaced screws. Safety concerns on the violation of the spinal canal leading to potential harm to vascular, neural, and other vital structures have necessitated the need to improve the accuracy of pedicle screw placement.

Spinal navigation is a computer-based surgical technology that improves intraoperative orientation to the unexposed anatomy during various spinal procedures. Computer-navigated surgery is a subset of computer-assisted spine surgery that is itself a part of both computer-assisted orthopedic surgery (CAOS) and computer-assisted neurosurgery.⁷ The term CAOS was coined by Thomas Kuhn to bring under a single umbrella a number of technologies based on computers such as computer-assisted surgery, medical robotics, computer-navigated surgery, image-guided surgery (IGS), spinal navigation, stereotaxic guidance, and computer-assisted medical intervention.⁸

Image-guided surgery is a combination of image acquisition and processing followed by intraoperative navigation. The overall aim of the spinal navigation procedure is to show the operating surgeon the exact position of the handheld instruments in relation to the bony anatomy, represented on an image displayed in the operating theater. The main goals of IGS are to improve the surgeon's hand-eye coordination, to improve accuracy of implant placement, to reduce radiation exposure to the surgeons, and to shorten the surgical time.

The application of navigation was initially limited to increased accuracy of pedicle screw placement in cervical spine, scoliosis, and revision surgeries. In the last decade, the applications has extended to include surgeries like excision of spinal tumors (e.g. osteoid osteoma and osteoblastoma) and excision of spinal pathologies such as ossified spinal ligaments and osteotomies of spine.

EVOLUTION OF SPINAL NAVIGATION

The current concept of image-guided spinal surgery has its roots in the field of neurosurgery. The concept of stereotaxis, which uses a frame as a reference device to perform invasive procedures, was developed for clinical use by Robert H Clarke and Victor Horsley for treating intracranial pathology.⁹ The specialities of both orthopedics and neurosurgery have been the forerunners in the implementation of IGS.

Nolte et al. in Switzerland developed the concept of interactive navigation of surgical instruments and Merloz et al. in France developed the concept of anatomically based registration using reference anatomical structures detected by intraoperative sensors.^{8,10} Simon and Foley developed this technology in North America.¹¹ They used anatomic landmarks on the dorsal aspect of the spine as fiducially (registration) markers in association with a dynamic reference array (DRA).¹² These anatomic fiducials provided reliable registration accuracy and augmented the flexibility of the system, as the registration points could be added or changed intraoperatively.¹³

Kalfas et al. also performed early investigational research using similar image-guided techniques to improve the safety of lumbar pedicle screw placement.^{12,14} The development of newer concepts of image segmentation, 3D model building, and registration formed the basis of frameless computer-assisted surgery. Major contributions toward this have been from Brown in 1992¹⁵ on two-dimensional (2D) photometric image registration followed by Van den Elsen^{16,17} on 3D-image registration. This led to

the development of second-generation computed tomography (CT) and fluoroscopy-based systems and along with it the use of navigation in complex procedures throughout the spine.

PRINCIPLES OF SPINAL NAVIGATION

Spinal image guidance systems are marketed by various manufacturers. Generally, these systems share the same basic functions and components with differences in software and hardware capabilities.

The standard IGS consists of the following components:

1. System of image acquisition and processing
2. Image processing computer workstation interfaced with two-camera electro-optical localizers (Fig. 135.1)

These systems have a referencing device, the DRA, which is attached to the patient during navigation. The DRA has attached LEDs (light-emitting diodes) and can be tracked by an electro-optical camera. The DRA enables

Fig. 135.1: Image processing computer workstation interfaced with two-camera electro-optical localizer.

Figs. 135.2A to F: Instruments used in computer navigation-assisted surgeries. From left to right: (A) Spanner. (B to D) Dynamic Reference Frame. (E) Reference Tracker with reflecting sphere. (F) Navigation probe (bottom).

accurate navigation even in the presence of motion (Figs. 135.2A to F). The LEDs are called the active arrays, as the light emitted by them is recognized by the electro-optical camera. Instrumentation is accomplished by specialized instruments (screw drivers, probes, drill guides, etc.) with attached reflective spheres. The reflective spheres are called the passive arrays as they reflect the infrared rays emitted by the camera. The infrared light that is transmitted from or reflected by these instruments is relayed to the computer workstation that calculates the precise location of the instrument tip in the surgical field as well as the location of the anatomical point on which the instrument tip rests.¹⁴ The relative position of the instruments and DRA is tracked by an optical camera to facilitate navigation.

Image Acquisition

The initial step in image-guided spinal surgery is the acquisition of multiple successive images of the region of interest. Image acquisition can be preoperative or intraoperative and can be accomplished with either fluoroscopy or CT.

Preoperative CT-Based Image Guidance

Preoperatively CT scan of the planned vertebral level is acquired using standard protocol. The images are obtained using thin, contiguous axial slices (1–3 mm). The scan data is transferred to the computer workstation. The computer workstation reconstructs the data into axial, coronal, and sagittal views of the spine.

Intraoperatively the first step of navigation is patient registration. After exposure of the spine, DRA is attached firmly to spine that is usually the spinous process. Registration is then performed using the registration probe fitted with LEDs by paired-point matching and surface matching technique. This information allows the computer workstation to create a contour map of vertebrae. The preoperative CT-based image guidance is associated with the following disadvantages:

- The need for preoperative CT scan. The scan should be performed using a specific protocol, and hence if patient already has a CT scan it will add to cost and time and also radiation exposure.
- The registration process has a learning curve and is time-consuming, and takes on an average of about 3–5 minutes.¹⁴
- Registration process needs to be repeated many time during surgery depending on the length of fixation and this affects the duration of surgical and navigational procedure.¹⁸
- The preoperative CT data is acquired with the patient in different position than at the time of operation. This could be problematic in patients with instability like trauma and degenerative instability. This may lead to movement and changes in position during intraoperative positioning leading to navigational inaccuracy.
- The process of registration paired patient matching and surface matching depends on exposed spinal anatomy. This limits its use in minimal invasive procedures.

Virtual Fluoroscopy

This is a technique that merges the standard 2D C-arm fluoroscopy with image-guided navigational technology. Anteroposterior, lateral, and oblique views are obtained with a fluoroscope with an attached calibration target. The images are then automatically transferred to the IGS that then correlates the data with the intraoperative spinal anatomy. The main advantage of virtual fluoroscopy is that it uses the standard C-arm image intensifier that is available in the operation theater and the familiarity of the surgeon to the system. In addition, virtual fluoroscopy also eliminates manual registration and reduces radiation exposure operative time. The main drawback is that the technique provides the surgeons with only anteroposterior and lateral planar images. The pedicle screw fixation depends on the position of screw in the axial plane. It is

Figs. 135.3A and B: Siemens SIREMOBIL Iso-C three-dimensional (3D) automatically rotates through a 190° arc about the patient to obtain 3D images.

important to demonstrate the relation of screw relative to the spinal canal. The quality of image is dependent on the resolution of acquired fluoroscopic images. This will be of disadvantage and can affect navigation in osteoporosis, obese patients, and deformity.

Intraoperative 3D C-Arm Fluoroscopy

This technique combines an isocentric C-arm fluoroscope with an image-guided navigational technology. Isocentricity ensures that the central focus is precisely maintained, while C-arm is moved in the angular and orbital direction. In switching between anteroposterior and lateral views, there is no need to adjust the C-arm horizontal travel in and out. Unlike a standard fluoroscope, an isocentric C-arm is able to automatically rotate around the patient through a 190° arc while maintaining the relative spinal anatomy in its center (Figs. 135.3A and B). The image can be acquired in 2 minutes cycle (100 high-resolution images) or 1 minute cycle (50 low-resolution images). The addition of specialized software Iso-C to C-arm allows this technology to effectively work as a CT scanner. The images are then reconstructed to provide axial, coronal, and sagittal views of the anatomy. The Iso-C-arm is fitted with a customized reference frame. The DRA is attached to a fixed point on the patient's spine. During image acquisition, the electro-optical camera tracks the position of DRA in relation to the C-arm during image acquisition.

The images are reconstructed in to sagittal, axial, and coronal format and then transferred to the navigation

workstation. This technique allows automated registration eliminating the need for manual registration.

Advantages of Iso-C Based Navigation

- Does not require preoperative CT scan with the image-guided protocol and hence saves money.
- Since the image acquisition is intraoperative, the concern of navigational inaccuracy on positioning is eliminated.
- Automated registration eliminates manual registration and hence saves time.
- The position of implant, adequacy of tumor removal, etc. can be confirmed by obtaining a postprocedure scan intraoperatively.
- Can be used safely in percutaneous and minimal access surgery.
- The isocentric-C-arm can serve as a standard C-arm fluoroscope, allowing a single device to serve as both C-arm and during image-guided cases.

Disadvantages of Iso-C Based Navigation

- Axial reconstructions that are of lower resolution than those available with CT scans (Figs. 135.4A and B).
- Like all fluoroscopic technique, the quality of image is dependent on the resolution of acquired fluoroscopic images. This will be of disadvantage and can affect navigation in osteoporosis, obese patients, and deformity.
- The working area is only a 12 × 12 cm long segment and hence the procedure will need multiple image acquisitions.

Figs. 135.4A and B: Images acquired from computed tomography-based navigation (A) and Iso-C-arm based navigation (B).

Intraoperative CT-Based Navigation

- O-arm
- Intraoperative CT suite.

O-Arm Navigation System

It is an intraoperative imaging that uses the flat panel detector technology to improve intraoperative image

Figs. 135.5A and B: O-arm navigation system with flat panel detector.

acquisition and quality. It can provide standard fluoroscopic image or 3D CT scan. The O-arm consists of an oval telescopic gantry that obtains images in a 360° arc (Fig. 135.5A and B). The O-arm gantry is automatically adjusted by a motorized robot. The X-ray tube and the flat planar are located within the oval unit. The field of view of O-arm is 30 × 40 cm, and hence it can scan up to six vertebral levels in an adult patient. The images are obtained intraoperatively, while a DRA is attached to patient. The images are transferred to a workstation resulting in multiplanar reconstruction and automated registration. Higher resolution images can be obtained with 750 pulses over 25 seconds, while reconstruction images require 391 pulses over 13 seconds.¹⁹ Postprocedure O-arm can be used as a standalone CT scanner to confirm screw placement, spine decompression, tumor resection, and alignment.

Full rotation 3D intraoperative imaging using O-arm imaging system offers the following benefits over Iso-C based 3D navigation:

- Faster rotation time results in shorter image acquisition time
- Improved resolution and thus higher quality images
- Larger field of view
- *Reduced radiation exposure:* The radiation exposure is about (2.09–5.45 mGy) for spine that is much less than conventional CT.

Brain Suite Intraoperative CT

Brain suite by Brain lab combines VectorVision sky navigation with an intraoperative CT scanner and operating

table with a radiolucent table top (Figs. 135.6A and B). The CT scanner is a sliding 40 slice gantry with an enlarged bore diameter of 82 cm. The image data is transferred directly from scanner into the navigation system. This technology makes it possible to anatomically register images taken intraoperatively. It allows enhanced decision process by improving surgical navigation, planning, data management, integration, and image registration. The intraoperative CT (iCT) navigation allows easy navigation with high accuracy. The data acquisition time is short and can acquire CT data of the whole spine. The iCT can replace an additional preoperative scan and is useful to assess spinal correction and osteotomy. The comparison between various navigation systems is shown in Table 135.1.

Reference System

The accurate translation of spatial information into detailed renderings of spinal anatomy necessitates a stable frame of reference that enables the IGT computer to calculate the relative positioning of instruments within the surgical field in all three dimensions, usually with a consistent magnitude of error of no more than 2–3 mm.^{20,21} The registration process serves to establish a precise spatial relationship of the image data with the physical space of patients corresponding surgical anatomy.²² The registration process can be performed either with the tracking device (fixed position marker) or without the tracking device (fiducial marker).

Figs. 135.6A and B: Brain suite intraoperative computed tomography.

Fiducial markers are attached to multiple distinct anatomic landmarks that serve as registration points. Then the paired point registration is performed by selecting at least three corresponding points in a CT and in the exposed anatomy. Increasing the number of points will enhance the accuracy of the registration process but is associated with increased duration. This is usually combined with the surface matching as a supplementary registration technique. Surface matching involves selecting multiple points on the exposed surface of the spine in surgical field (Fig. 135.7). This information is transferred to a workstation, and a topographic map of selected anatomy is created and matched to the patient and to the patient image set²². In a long level fixation necessitating multiple registration processes, the duration of navigated procedure will be significantly prolonged. Image-guided navigation without tracking device is subjected to patient movement either by respiration or leaning on the table.

The spinal tracking device consists of passive reflectors mounted on a small frame. This reference frame is attached to exposed spinal anatomy that is usually the tip of spinous process and its position is tracked by infrared camera system. Any movement of the spinal anatomy alerts the navigation system that makes appropriate calculation to maintain accuracy. This when used with fluoroscopic and iCT-based image acquisition can perform an automated registration. This technique involves attachment of a reference frame on the exposed spine and a second reference frame on the fluoro or the CT scanner. Once the image is acquired, the data is transferred to the navigational system that then performs an automated registration eliminating the need for manual registration. The disadvantages are the need for maintaining a line of sight between the reference frame and optical camera, hindering of the movement of the surgeon, and displacement of the reference frame that will affect the accuracy of navigation.

Table 135.1: Comparison between various navigation systems.

<i>Image-guided surgery</i>	<i>2D fluoroscopy</i>	<i>3D fluoroscopy</i>	<i>Preoperative computed tomography</i>	<i>O-arm</i>	<i>Intraoperative</i>
Registration	Automated	Automated	Manual and time-consuming	Automated	Automated
Registration duration	Short	Short	Long	Short	Short
Image display	2D [anteroposterior (AP) and lateral]	3D	3D	3D	3D
Scan time	Only AP and lateral radiographic images	2 minutes	30 seconds	40 seconds	30 seconds
Number of vertebrae in single scan	3–5 vertebrae	3–5 vertebrae (working area 12 × 12 cm)	Whole spine	6–8 vertebrae (working area 30 × 40 cm)	Whole spine
Bone image quality	Poor	Poor	Good	Good	Good
Imaging in severe deformities	Not possible	Not possible	Possible	Possible	Possible
Carbon table and carbon head clamp fixation	Not necessary	Required	Not necessary	Required	Required
Ideal area of the spine	Lumbar spine	Whole spine	Whole spine	Whole spine	Whole spine
Minimally invasive spine surgery	Difficult	Possible	Not possible	Possible	Possible
Real-time imaging	Yes	Yes	No	Yes	Yes

(2D: Two-dimensional; 3D: Three-dimensional).

**Fig. 135.7:** Surface matching.

Tracking System

Image-guided navigation utilizes either optical or electromagnetic (EM) tracking systems. The optical localizer tracks infrared light emitted by a series of LEDs mounted on a customized handheld navigational probe or selected

surgical instruments. Alternatively, the optical localizer itself can be the source of infrared light that is continuously reflected back to the camera by passive reflectors attached to the probe or selected surgical instruments²² The successful function of these optical systems is dependent on a clear “line-of-sight” between the tracking device and the surgical field, so hand movements that disrupt this connection will impede the navigation process (Fig. 135.8).

In the EM system, three orthogonal EM fields are generated by a transmitter attached to a fixed anatomic reference point such as a spinous process. The positional data of these instruments are collected by a receiver and is integrated by the computer processor to facilitate navigation.²¹ The main advantage is that an unobstructed view between the transmitter and receiver is not required, allowing the surgeon and nursing staff to work freely within the operative field. The disadvantages include interference of EM image guidance by metal artifact and EM fields originating from operating room equipment (e.g. monopolar electrocautery, electrocardiogram monitoring). Because of the limited area of these EM, the transmitter needs to be repeatedly transferred to obtain sufficient tracking information for multilevel procedures.

Fig. 135.8: Intraoperative theater setup of navigation gadgets. The dynamic reference array (red arrow) has been attached to the patient's spine and kept horizontal to be seen by the optical localizer system (green arrow). The Iso-C C-arm rotates around the operative site capturing multiple images that are then transferred to the localizing platform.

Technique of Navigated Pedicle Screw Fixation

The first step in navigation is registration. After registration, the accuracy of registration is confirmed by placing the navigational probe on the exposed surface land marks like spinous process, lamina, transverse process and moving the probe on the lamina. The computer workstation should display the probe tip touching corresponding points on the CT data. If the position of probe on the patient and computer do not match, there is registration and localization error and the whole process of registration should be repeated. This verification step represents a more absolute indicator of registration accuracy and is important to perform prior to proceeding with navigation. After the verification step has been completed, the spinal anatomy previously hidden from direct surgical view is now easily visualized on the workstation monitor in multiple planes. When the navigational probe is placed directly perpendicular to the long axis of the spine the image will be in the sagittal, coronal, and axial plane. The reformatted image will change depending on the angle between the navigation probe and spine. As the probe is moved to a different location, the reformatted image and trajectory line will change (Figs. 135.9A to D). Thus, the navigated

system will provide better anatomical information of the spine. Instruments used for pedicle screw fixation can be precalibrated or intraoperatively calibrated. Precalibrated instruments are automatically recognized by IGS and are immediately available for use. Intraoperative calibration needs registration of each instrument for it to be recognized by the IGS and hence it is time-consuming (Figs. 135.10A to D).

The probe is used to confirm the starting point of pedicle screw fixation and pilot holes are made with a high-speed burr or awl to enter the cortex. The estimated trajectory and recommended size of the implant are superimposed on multiplanar images of the selected level. The surgeon makes a mental note of this trajectory and instrumentation proceeds in a standard manner. At each stage of instrumentation that precedes insertion of the pedicle screw, the trajectory of the implant can be confirmed with the specialized probe. The integrity of the pedicle wall can be confirmed by a pedicle feeler.

Advances in Spinal Navigation

Spinal planning software iPlan spine developed by Brain lab is a surgical planning software to create a strategic treatment plan for procedures performed with spinal navigation and tumor surgery. The software uses multiple data-sets such as CT and magnetic resonance imaging (MRI). Preoperative CT-MRI merging helps in detailing the bone and soft tissue extent of tumors and hence it is resection.

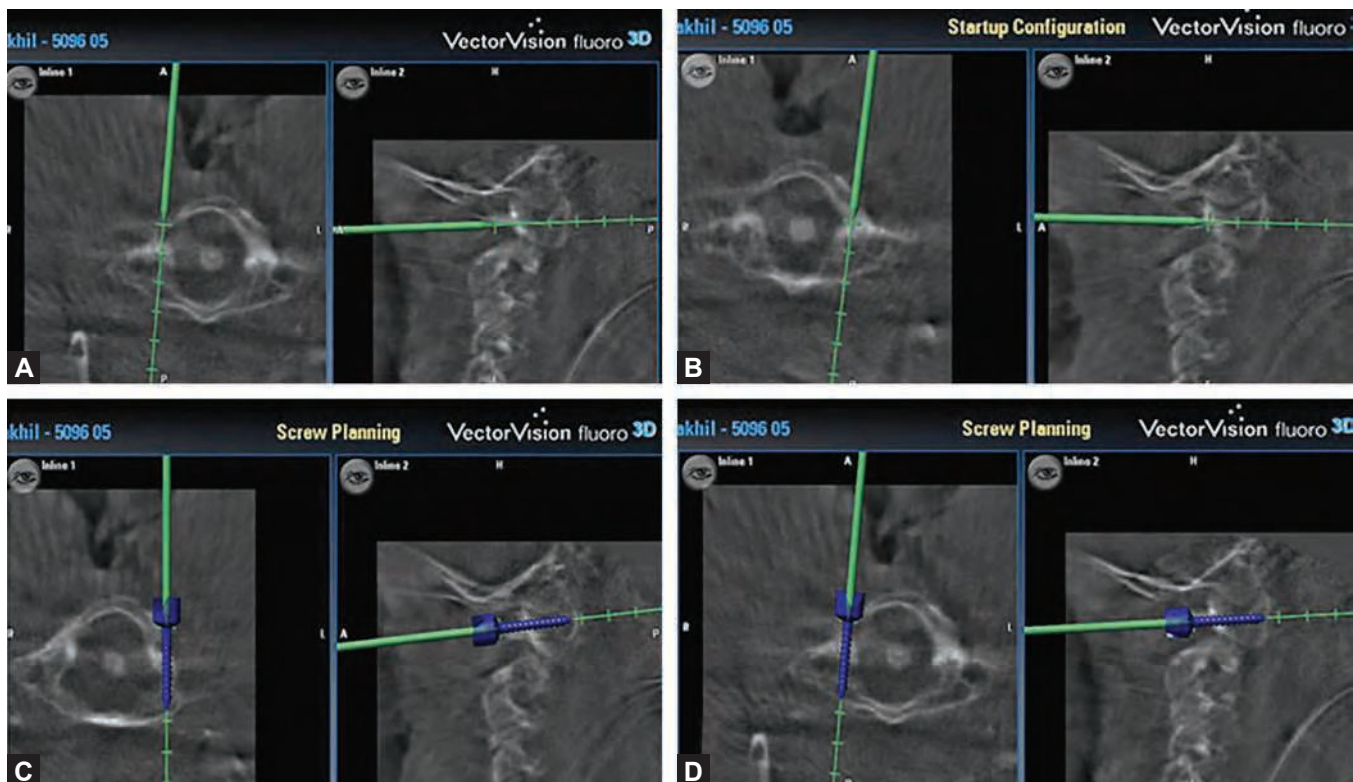

The current navigation systems collaborating with implant manufactures provide navigation ready pedicle instruments, K-wires, and drill guide to make instrumentation simpler and faster.

Concerns of Spinal Navigation Surgery

Even though spinal navigation has been existent for about two decades, it is yet to gain general acceptance among surgeons. This lack of acceptance has been attributed to increased operative time, learning curve, and complexity of navigation. The concerns in spinal navigation surgery are accuracy, operative time, radiation, learning curve, and cost-effectiveness.

Accuracy

The demands concerning the accuracy of image-guided procedures vary depending on the type of procedures, e.g. ventral or dorsal, anatomy of the spine (normal curvature

Figs. 135.9A to D: Workflow of navigation: the navigation probe helps to ascertain the exact entry point for a screw (A), the direction and trajectory of the screw (B) and the width and the length of the screws (C and D).

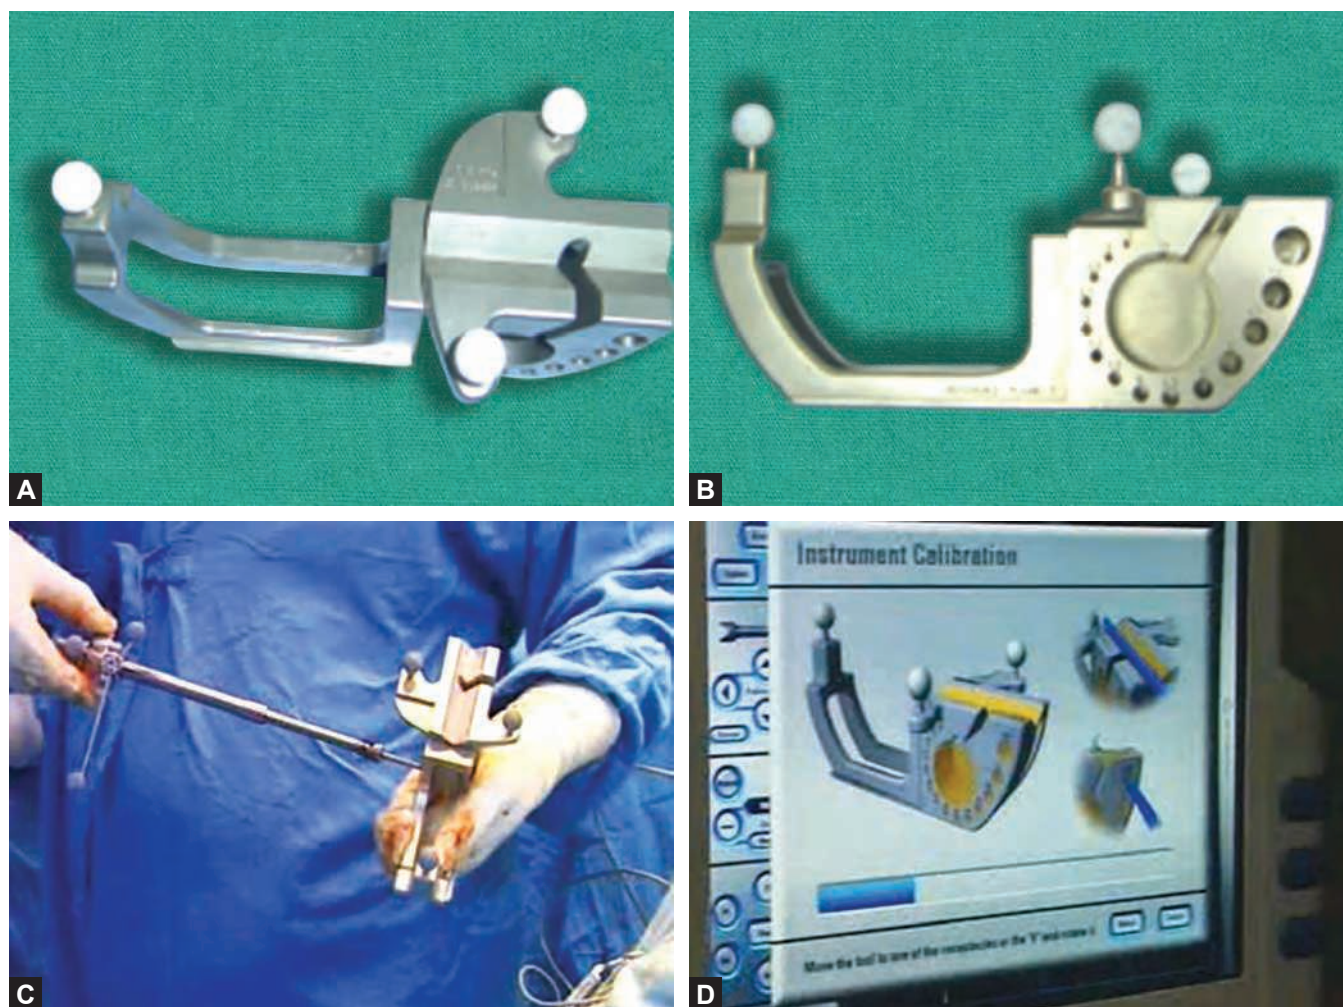

or deformed), and the level of the spine subjected to surgery. In the cervical spine, the overall accuracy is very good with a maximum displaced rate of 8% reported by Acosta et al.²³ compared to 22% of misplaced screws in conventional techniques. The displacement rates of 8% may be attributed to the small size and complex anatomy of the pedicles, resistance offered by the musculature while inserting screws and the relative mobility of cervical spine during the procedure.

In the thoracic and lumbar spine, navigation-based studies have shown pedicle perforation rates between 1% and 5%. Silbermann et al.²⁴ reported a higher accuracy rate by 5% points for pedicle screw placement using O-arm navigation compared to 2D fluoroscopy/CT group (99% vs. 94.1%). Tian et al. have shown that 3D-based navigation system (CT and 3D Iso-C based navigation) provides more accurate pedicle screw insertion over 2D fluoroscopy-based navigation system.²⁵ The superiority of navigation system is more obvious when they were applied to abnormal spinal structure. Overall image-guided surgery increases the accuracy of pedicle screw placement but

does not completely prevent instrumentation misplacement. This has been attributed by Tjardes to the human factor involved in IGS, i.e. the surgeon.²⁶

Operative Time

One of the major concerns with the use of spinal navigation is the increased operative time. The time taken to insert a pedicle screw using IGS depends on experience of the surgeon, familiarity with the navigation system, the registration process, and the need for single or multilevel registration. The use of automated registration process using Iso-C C-arm and iCT has shortened the duration of the procedure significantly. A meta-analysis by Shin et al.²⁷ showed no difference in the operating time between navigated and non-navigated pedicle screw. Patil et al. reported a mean time for screw placement of 5.9 minutes using navigation that was slightly longer than previously reported for screw placement using conventional techniques (5.1 minutes) but shorter than the preoperative CT navigation method, 7.5 minutes per screw.²⁸ Rajasekaran et al. reported a significantly shorter time required to insert

Figs. 135.10A to D: The calibration guide and intraoperative calibration of the pedicle screw.

a pedicle screw using 3D Iso-C-arm in scoliosis. In their study, the average screw insertion time in the non-navigation group has 4.61 ± 1.05 minutes compared to 2.37 ± 0.72 minutes in the navigation group.²⁹ Shin et al. have shown that the mean time for insertion of a pedicle screw was 3.79 minutes in the fluoroscopy guided group and 4.45 minutes in O-arm navigation-guided group.³⁰ The mean preparation time for screw placement was about 19 minutes in navigation-guided group, compared to only 4 minutes in fluoroscopy-guided group.

The iCT, as a result of its ability to allow for multiple level registration, significantly reduces the time for pedicle screw insertion and therefore mean total operative time in comparison with single level registration. Cui et al.³¹ in their analysis of iCT navigation noted a mean iCT scanning time of about 17 seconds for the whole spinal column and a mean time-out for intraoperative scanning of about

6 minutes. In spinal navigation combined with the intraoperative 3D imaging modality, the implantation time of the pedicle screw becomes simplified, more accurate and safe with shorter operative time.

Radiation

One of the major advantages of IGS is to minimize radiation exposure to the surgeon, assistants, and the operating room personnel. When compared to other procedures in musculoskeletal surgery, spine surgery is radiation intensive. The work by Rampersaud et al. demonstrated that for the spine surgeons, radiation exposures is up to 10–12 times greater than in other orthopedic procedures, and may approach or exceed guidelines for cumulative exposure.³² Radiation dose varies based on the total fluoroscopic time, type of machine, and the position of the

image intensifier. In IGS, there is less radiation exposure both in the amount of time of radiation exposure and in the total radiation dose that is used intraoperatively.³³

Gebhard et al. showed that image-guided approaches generally reduce the radiation exposure of the operating room personnel independent of the registration mode compared to standard fluoroscopy-assisted surgery.³⁴ The best results were found for 3D-fluoroscopically assisted approaches with a 10-fold reduction of radiation exposure compared to standard fluoroscopy-assisted procedure.³⁴ This is because that when image acquisition is being performed, the surgeon and operating room staff stand outside the theater or behind a lead shield. Of concern is the amount of radiation exposure to the patient. In the preoperative CT-based image-guided navigation system, because of the necessity for thin-sliced, high-resolution CT scans, the overall radiation exposure to the patient is significantly higher. This can be reduced by using an optimized sequential CT protocol. The new-generation scanner, by using new technologies like dose modulation, tube current modulation, and filtering, uses less radiation. The amount of irradiation of O-arm is only 60% of the ordinary CT scan (data from Medtronic, USA).

Cost-Effectiveness

The use of IGS adds to the cost of surgery. This is particularly applicable to iCT-based systems that will need radiation shielding, a larger operating room, and additional trained staff. The reduced incidence of neurological injury and reoperation rate, especially in complex anatomical areas like the cervical and upper thoracic spine, and complex pathologies like deformities and tumor, should offset some of the cost. The combination of IGS and minimally invasive spine surgery (MISS) may reduce the overall morbidity of spinal surgery with less surgical dissection, reduced hospital stay, early mobilization, and early healing. The economic study on the use of IGS by Costa et al. revealed a mean reduction of costs of about 17.7% per surgery when using navigation. This difference was mainly noted in the reduction of the operative time (about 30 minutes for the procedure) and the costs of pre- and post-operative CT scans.³⁵

Learning Curve

The concerns about the learning curve using IGS including accuracy and operative time have created some reservation about adapting to this technology. A survey of 147 spine surgeons regarding spinal navigation found that

the major weaknesses were longer operative time (63.5%), increased cost (48.3%), lack of necessity (40.7%), unreliable navigation accuracy (37.9%), and intraoperative glitches (35.2%).³⁶ However, it has been our experience that the surgical time decreases significantly after gaining familiarity with IGS. Wetzel et al. in a case cohort study demonstrated decreased screw perforation rate and operative time. The learning curve showed a drop after 6 months of using IGS that plateaued after 12 months. The majority of IGS education takes places in the OR, and the development of education and training modules using navigation technology will offer a way to develop and improve the capabilities to perform IGS.

Other Limitations of IGS

The movement of the reference frame by respiration and muscle retraction can result in erroneous information regarding spinal position, resulting in misplacement of an implant. The surgeon or the assistant may touch the DRA during the procedure causing loss of connection and movement of the frame. This can be prevented by fixing the DRA to a rigid stable bony structure such as spinous process or pelvic ring. Also, it is important that the accuracy check be repeated many times during the procedure to confirm the accuracy of the registration process. The movement of the surgeon between the DRA and the optical camera can interfere with navigation. This has been addressed by having ceiling-mounted optical cameras.

Clinical Applications of Spinal Navigation

The application of IGS navigation provides allows for improved understanding of surgical anatomy and facilitates the accuracy of implant placement. In addition, IGS also reduces the stress on the surgeon performing these complicated procedures. The experience of the surgeon and the complexity of the procedure are two important factors determining intraoperative surgical stress. Wetzel et al. in their paper on the effect of stress on surgical management reported that intraoperative stress affects judgment, decision making and communication. Studies have shown that the detrimental effects of these factors are related to errors and poor surgical outcome.³⁷

The spinal navigation technique was initially used to enhance the safety of pedicle screw insertion. In the past decade, refinements and advances in the technology have extended the use to decompressive procedures, deformity correction, tumor resection and minimally invasive

surgery (MIS). This has been largely possible due to the capability to merge the preoperative CT and MRI via the navigation system and the use of special precalibrated tools like an awl, screw driver, osteotome and k-wire drill guide.

Spinal Instrumentation

Pedicle screw fixation has gained acceptance as an effective and reliable method of spinal instrumentation. Pedicle screw fixation allows for multidimensional control and provides greater rigidity and improved fusion rates. Initially used in the lumbar spine, their use has extended to the thoracic and cervical spine. However, because of variation in the pedicle anatomy and the small size of the thoracic and cervical pedicle, the safe and precise placement of pedicle screws can be difficult. Despite the use of intraoperative fluoroscope and electrophysiological monitoring, the incidence of screw malposition remains high even in experienced surgeons. Various studies have shown that the pedicle violation can vary between 14% and 55% using standard techniques.³⁸ The accurate placement of pedicle screws is critical for successful outcomes. The malposition of pedicle screws carries risk to the neural elements, vascular injury, reoperation and pleural effusion associated with misdisplacement.^{39,40} Although many clinical studies report a low incidence of neurological injury associated with misplaced screws, there is evidence that small cortical breaches can impact the biomechanical strength of a construct.⁴¹

George et al.⁴² demonstrated the importance of cortical containment of pedicle screws in their findings that the pull-out strength of pedicle screws with a cortical breach was 11% less than that of screws contained wholly within the pedicle. The additional anatomic data provided by IGS improves the accuracy of pedicle screw fixation and reduces the risk of neurologic and vascular injury. Also, image guidance allows larger diameter screws to be placed and can result in screws being placed in a more medial trajectory resulting in increased construct stability.

Kosmopoulos et al.⁴³ in a meta-analysis showed that the rate of cortical violation by pedicle screws inserted without the use of navigation amounted to nearly 10%.

Cervical Spine Instrumentation

The instrumentation of the upper cervical spine has certain inherent problem due to the smaller size of osseous elements, higher incidence of anatomic variation, inconsistent landmarks in complex congenital anomalies and

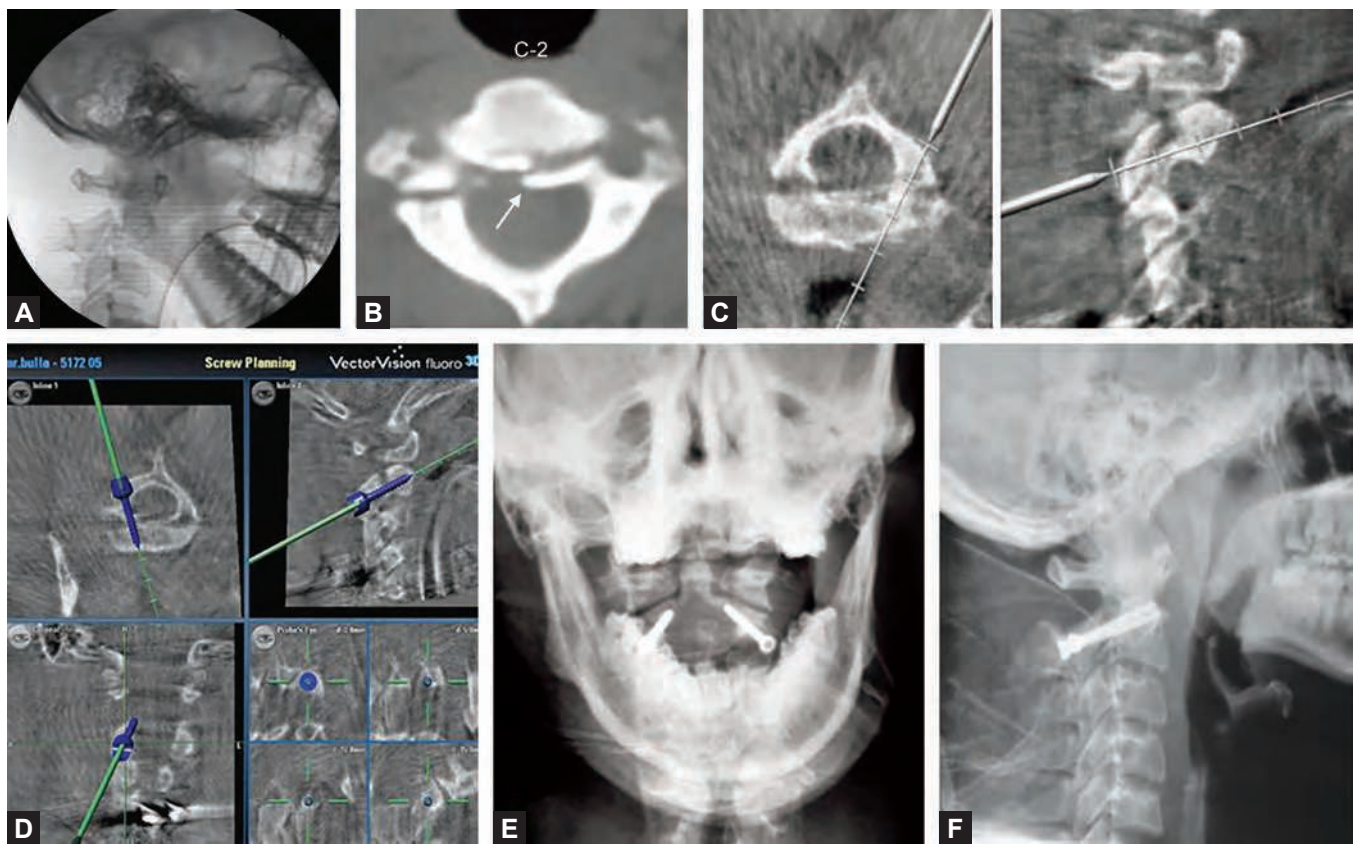

close proximity of vital neurovascular structures.⁴⁴ The C1–C2 transarticular screw provides higher fusion rates but is contraindicated in about 20% of patients due to variation in vertebral artery anatomy.⁴⁵ C2 pedicle screw placement theoretically should avoid injuring the vertebral artery. However, the presence of a high residing C2 transverse foramen, vertebral artery erosion of the pedicle and an anomalous vertebral artery increases the risk of injuring the artery. In a multicenter study on C1–C2 fusion in 102 adult patients, Aryan et al. were not able to identify the C2 pedicle in 23 patients (22%). The vertebral artery also had a variable course in >25% of these patients, forcing them to use alternative methods of fixation.⁴⁶

Application of IGS in Upper Cervical Spine

- C1–C2 transarticular fixation
- Segmental C1–C2 screw fixation
- Anterior odontoid screw fixation
- Transoral surgery
- Direct repair of a hangman's fracture.

Bolger and Wigfield,⁴⁷ in a retrospective review, did not observe any neurological or vascular injuries following C1–C2 transarticular screw placement performed using navigation. Marcus Ritcher et al.⁴⁸ analyzed 22 patients following C1–C2 transarticular screw placement using navigation. The screw position was evaluated postoperatively using CT with multiplanar reconstruction along the screw axis of each screw. None of the transarticular screws or pedicle screws were significantly (>2 mm) misplaced and no screw-related injury to vascular, neurogenic or bony structures were observed. No screw revisions were necessary. Rajasekaran et al.⁴⁹ and Attia et al.⁵⁰ have reported on the efficacy of navigation for screw fixation following traumatic atlantoaxial injury in children. C1–C2 rotatory instability is associated with rotation of C1 and C2, leading to alteration in normal anatomical landmarks and orientation. In a prospective study of 20 patients, Rajasekaran et al.⁵¹ demonstrated the safety of Iso-C navigation in the direct repair of the pedicle in hangman's fractures. Bilateral screw fixation was possible in 18 patients and the remaining 2 had unilateral screws because of significant fracture comminution. There was no screw malposition with all 20 patients showing evidence of fusion at an average of 8 weeks (Figs. 135.11A to F).

Yang et al.⁵² in a retrospective study compared anterior odontoid screw fixation between Iso-C based navigation and standard technique. The fluoroscopy time in the Iso-C 3D group was 42.9 seconds as compared to 68.1 seconds in the control group ($P < 0.01$). The mean operative time

Figs. 135.11A to F: Navigated direct repair of Hangman's fracture. Lateral radiograph image and axial computed tomography shows a hangman's fracture (A and B). The intraoperative navigation image shows the fracture line and the planned screw trajectory and dimensions (C and D). Postoperative anteroposterior and lateral images show the reduced fracture has been fixed with pedicle screws. (E and F) Pedicle-based cortical screws.

was 91.5 minutes in the Iso-C 3D group compared with 81.6 minutes in the control group ($P = 0.20$). The procedure required the DRA to be attached to the Mayfield clamp for registration. Image guidance in anterior odontoid screw fixation obviates the need for cumbersome biplanar fluoroscopy allows for intraoperative image acquisition after surgical exposure, reduces intraoperative registration time, reduces both surgeon and patient radiation exposure and allows immediate computerized topographic imaging in the operating room to verify screw position.⁵³ The authors have also used Iso-C navigation in the reduction and fixation of unstable C1 burst fractures with good results. Iso-C based navigation assisted in confirming intraoperative reduction of the fracture, identifying the screw entry point and the direction of C1 lateral mass screw trajectory and final screw position.

Cervical pedicle screw provides significantly greater stabilization and stronger pullout strength than lateral

mass screws. They are ideal fixation points in patients with severe deformities of the cervical spine such as in rheumatoid arthritis that may require correction of a complex cervical deformity.⁵⁴ The complex anatomy of the normal cervical spine including the narrow diameter of the pedicles, the variations in the sagittal and axial angulations of the pedicles as well as the anatomical variations in the course and size of the vertebral artery makes cervical pedicle screw instrumentation a challenging procedure. Abumi et al.⁵⁵ using conventional techniques reported a perforation rate of 6–7% (45 of 664 screws) with 2 screws causing radiculopathy. Kotani et al.⁵⁶ compared navigated and non-navigated pedicle screws placement and found reduced rates of pedicle screw breaches (6.7% vs. 1.2%) in the navigated group. There was a 2% complication rate in the manual group, whereas the navigated group had no adverse events. Ishikawa et al.⁵⁷ and Ito et al.⁵⁸ using image-guided pedicle screw placement reported a screw

malposition rate of 2.8% with no neurovascular complications.

Rajasekaran et al.⁵⁹ performed a prospective study evaluating the accuracy of pedicle screw placement in children with cerebral palsy with complex cervical deformities. Of the 55 cervical pedicle screws placed, 88.3% were fully contained, 11.7% had a noncritical breach and none had a critical breach. Rajan et al.⁶⁰ demonstrated that in cervical deformity, of the 98 cervical pedicle screws placed using navigation, there was a high rate (90.8%) of what they termed “perfectly placed screws” leading them to conclude that the Iso-C 3D technique increased the accuracy of screw insertion.

In contrast to several reports demonstrating an advantage of a navigation system in the improvement of accuracy, there have been some criticisms of its effectiveness. Ludwig et al.⁶¹ experimentally compared the accuracy of manual insertion with computer-assisted screw placement, demonstrating no significant improvement in the computer-assisted group. This may have been due to the fact that the instrument guide tube with light-emitting diode was navigated only on the surface of the lamina, and the actual tip of the awl and screws were not directly visualized on the navigation monitor during each step of the screw insertion. We have found that the use of calibrated instruments for cervical pedicle screw insertion provides accurate, 3D and real-time instrument tip information, serving as an effective tool for safe and reliable pedicle screw placement in the cervical spine.⁵⁶

The results of the above mentioned studies clearly demonstrate that spinal navigation reduces but not eliminate the risk of screw malposition.

Thoracic Spine Instrumentation

Thoracic pedicle screws are an optimum anchor points because of their biomechanical superiority, increased tolerance of corrective force application and sparing of motion segments. However, thoracic pedicle screw placement in the upper and mid-thoracic spine is challenging due to size constraints. In the thoracic spine, the pedicles are narrow and the canal cord ratio is low; hence, the chance of a pedicle violation causing cord injury is common. Even in the normal thoracic spine the difficulty in obtaining high-quality intraoperative anteroposterior, lateral fluoroscopic view adds to the complexity of pedicle screw fixation.

Vaccaro et al.³⁸ placed 90 screws in the T4–T12 pedicles of five fresh-frozen cadavers and determined that 41%

violated the pedicle wall. Various studies using freehand technique pedicle screw placement have demonstrated a 14–55% misplacement rate and 1–8% neural injury due to malposition.^{39,40,43} Kim et al.⁶² examined the feasibility of IGS placement of thoracic pedicle screws in cadavers; while the overall rate of cortical screw perforations was 19.2%, the accuracy of the procedure increased considerably as the learning curve was overcome. Kosmopoulos et al.⁴³ performed a meta-analysis of the current literature and found that navigation provided higher accuracy in the placement of pedicle screws for the subgroups presented. Overall, the placement accuracy in the in vivo navigation-assisted subgroup (95.2%) was higher than that in the un-navigated subgroup (90.3%). The report included 130 studies with a total of 37,337 implanted pedicle screws.⁴³ Comparing 2D and 3D navigation systems Tian and Xu reported that CT navigation resulted in a higher accuracy rate than 2D navigation but provided a lower accuracy than the 3D fluoro group.⁶³

Shin et al.²⁷ conducted a meta-analysis of perforation risk for computer navigated versus freehand insertion. The study included 20 studies and a total of 8,539 screws (4,814 navigated and 3,725 non-navigated). In their analysis, there was a significant lower risk of pedicle perforation for image guided pedicle screw insertion than that for non-navigational insertion for all regions of the spine with an overall pedicle perforation risk of 6% for IGS and 15% for non-navigational insertion. The meta-analysis importantly did not reveal a significant difference in total operative time when comparing the two techniques.

Larson et al.⁶⁴ in their study, demonstrated a lower accuracy rate for pedicle screw placement with navigation in children compared with adults (96.4% vs. 98.2%). They hypothesized that the lower accuracy rate in children may be due to small pedicle size and possibly greater deformity.

■ DEFORMITY SURGERY

Application in Thoracic Spine Deformities

Pedicle screw instrumentation is the preferred method of posterior stabilization of the spine especially in the presence of deformity. It has the advantages of three column fixation, improved coronal, sagittal, and rotational correction, lower incidence of implant failures when

compared with conventional hook and wire constructs. In the presence of deformity, the size and orientation of the thoracic pedicles vary considerably between the different vertebrae within the curve, and also between the concave and convex sides of the same vertebrae. The pedicles are frequently thinner and sclerosed, making canal perforation a significant problem. The dura is often stretched over the pedicles on the concave side of the curve, and even minor medial violations can damage the cord. Hence, pedicle screw instrumentation is challenging as there are potential risks of iatrogenic damage to neural or vascular structures. Hicks et al.⁶⁵ in a systematic review of complications of pedicle screw fixation in scoliosis surgery, found a malposition rate of 15.7% per screw inserted confirmed with postoperative CT scans. Modi et al. reported that only 73% of the screws were accurately placed in 37 neuromuscular scoliosis patients with a mean Cobb's angle of 82° using the freehand technique.⁶⁶ Also, the reported reoperation rate in the literature due to implant malposition is about 5% in deformity correction surgeries.⁶⁷

Fortunately, the use of IGS has shown to improve the accuracy, decrease the operative time, and the radiation exposure in these complex surgeries. Navigation also allows safe insertion of pedicle screws by the in-out-in technique in pedicles that are sclerosed and too thin to accept a screw.

A study by Laine et al. on a 100 patients, including a small number of spinal deformity patients, demonstrated that the screw perforation rate significantly decreased from 13.4% to 4.6% with the use of computer navigation in the thoracic and lumbar spine.⁶⁸

Rajasekaran et al.²⁹ performed a randomized controlled trial that compared navigated (Iso-C 3D-based) and non-navigated placement of pedicle screws in scoliosis. They looked at 27 patients with scoliosis and 6 with kyphosis, with a total of 478 screws being inserted. Pedicle screw accuracy was much better in the navigated group with only a 2% breach rate compared with 23% in the non-navigated group. Additionally, the screw insertion time was much less in the navigated group, 2.37 ± 0.72 minutes compared with 4.61 ± 1.05 minutes in the non-navigated group including the time required for the C-arm to be moved into the operative field (Figs. 135.12A to F).

In a comparative study on the accuracy of pedicle screw placement in scoliosis between conventional fluoroscopic and computer-assisted surgical techniques, Kotani et al.⁵⁶ observed a perforation rate of 11% in the conventional group and 1.8% in the navigated group.⁶⁹ The improved

accuracy of intraoperative CT-based IGS in the insertion of pedicle screws in deformity has been demonstrated in the recent papers by Cui et al.³¹ and Larson et al.⁷⁰ Larson et al. reported on the use of O-arm based navigation in pediatric congenital deformity and reported a 99.3% screw accuracy rate.

The advances in spinal navigation techniques, such as planning software and precalibrated instruments, have made it possible to extend the use for correction of complex of deformities through vertebral osteotomy techniques. Fujibayashi⁷¹ demonstrated the safety and utility of computer-assisted surgical planning and image-guided surgical navigation in the planning and execution of major osteotomies in order to correct severe kyphoscoliosis. The IGS and CAS (computer-assisted surgical) planning significantly reduced the difficulty of operating through the fusion mass when planning both the osteotomy and pedicle screw placement (Figs. 135.13A to D).

Application in Cervical Spine Deformities

The presence of a deformity and altered anatomy (due to congenital anomalies) adds to the difficulty in performing cervical pedicle screw fixation. A study by Kotani et al.⁵⁶ of 17 patients, most of who had a cervical deformity, demonstrated a reduced screw perforation rate using computer navigation from 6.7% to 1.2%. Rajasekaran et al.,⁵⁹ as previously mentioned, again demonstrated improved screw accuracy placement in children with cerebral palsy and cervical deformity. He noted that of the 55 screws placed, 88.3% were fully contained, 11.7% had a noncritical breach and none had a critical breach (Figs. 135.14A to I). Rajan et al.⁶⁰ showed that in cervical deformity, of 98 cervical pedicle screws placed using navigation, there was a high rate (90.8%) of what they termed "perfectly placed screws" leading them to conclude that the Iso-C 3D technique increased the accuracy of screw insertion. There are certain limitations of Iso-C based navigation in deformity surgery. In case of severe deformity, it is difficult to centralize the patient in both anteroposterior and lateral view using C-arm. In gross obesity, the arc of C-arm cannot move freely around the patient. In these situations, intraoperative CT navigation offers an advantage over Iso-C arm navigation. The iCT is an especially effective imaging modality in complex cervical deformity and may decrease reoperations due to implant malposition.³¹

Figs. 135.12A to F: Navigation in scoliosis. Navigation can be used to insert pedicle screws into deformed and rotated vertebrae with good accuracy. In this patient with idiopathic scoliosis of 58° magnitude, intraoperative Iso-C navigation-guided pedicle screws have been used to correct the deformity.

Lumbar Spine

Lumbar fusion surgeries have continued to evolve with clinical outcomes showing promising results. This has resulted in high number of instrumented fusion, with pedicle screws being the most common form of fixation. As in the thoracic and cervical regions, the placement of lumbar pedicle screws carries a risk of injury to nerve root if it breaches the inferior and medial pedicle wall or it can cause injury to dura and neural elements if the screw is angulated medially excessively. If the size of screw is too long, it can cause injury to the anteriorly lying vessels, leading to catastrophic intraoperative bleeding and vascular shock. Schulze et al.⁷² reviewed postoperative CT

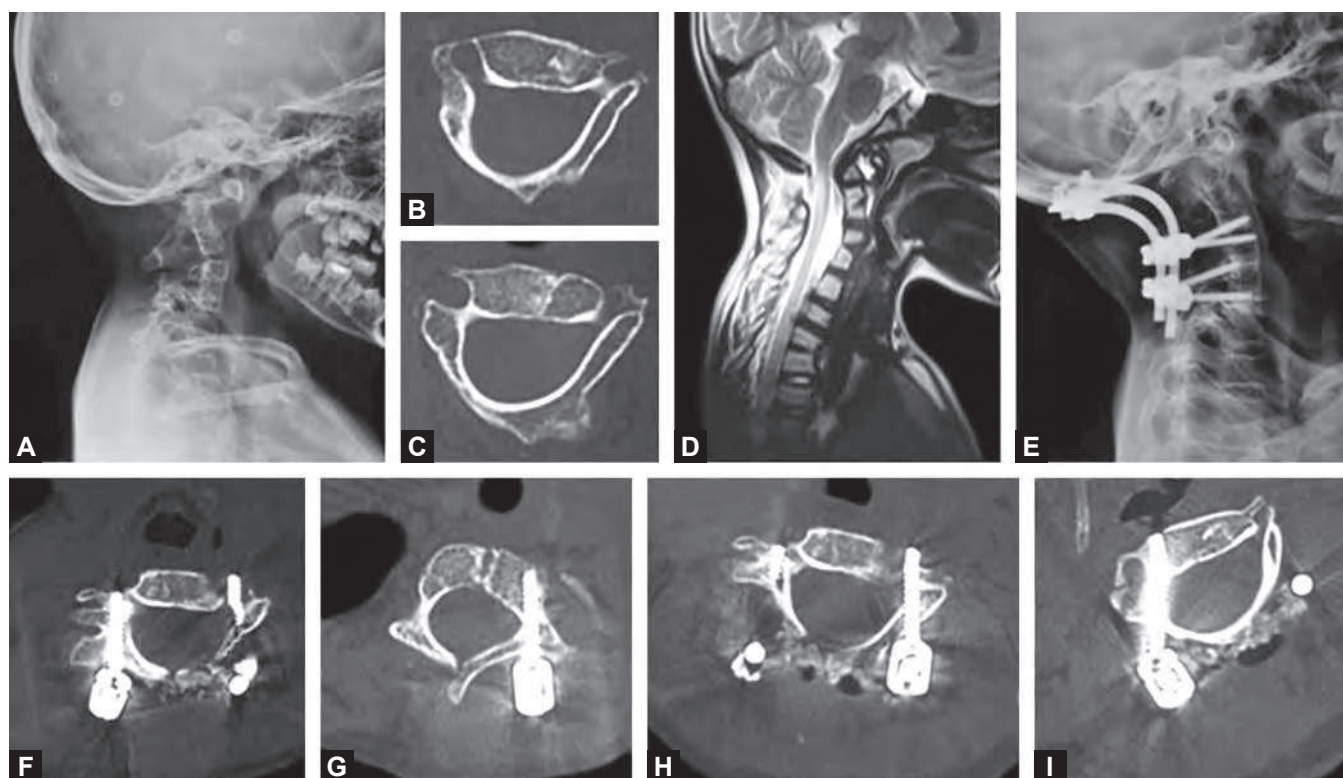

scans in a series of patients who underwent lumbar fusion procedures by experienced surgeons not using navigation and reported a 20% screw perforation of the pedicle wall.

Amato et al.⁷³ reported in 2010 on the accuracy of pedicle screw placement in the lumbosacral spine using conventional open techniques and intraoperative fluoroscopy followed by postoperative CT in 102 consecutive patients. The rate of frank pedicle screw misplacement was 5% of which two patients had radicular pain and a neurological deficit.

The concept for applying image guided therapy (IGT) to lumbar pedicle screws was established in a laboratory study by Foley and Smith. They performed a cadaver study using image guidance and demonstrated via postoperative

Figs. 135.13A to D: Navigated correction of post-traumatic deformity. Lateral radiograph demonstrates a post-traumatic thoracolumbar deformity (A). Intraoperative navigation images demonstrate the planned osteotomy level (B). Intraoperative picture (C) and postoperative radiographs show good correction of the deformity (D). Postoperative anteroposterior and lateral radiographs show good correction of the deformity.

Figs. 135.14A to I: Cervical pedicle screw instrumented occipitocervical fusion in an 8-year-old child. (A) Lateral radiograph of the cervical spine showing cervical segmentation anomaly with atlantoaxial instability. (B and C) Axial computed tomography (CT) images showing atypical attenuated dysmorphic pedicles at C3 and C4 levels. (D) Sagittal MRI of the cervical spine showing atlantoaxial instability with cord compression at the craniocervical junction. (E) Lateral X-ray of the cervical spine shows reduction of atlantoaxial instability with subaxial cervical pedicle screws and occipitocervical fusion. (F to I) Axial CT images showing well-contained cervical pedicle screws without any pedicle breach at C3 and C4 levels.

CT scans and visual inspection no evidence of pedicle wall violation. Kalfas et al.¹⁴ using image guidance inserted 150 lumbar pedicle screws in 30 patients and found that 149 of the screws were placed satisfactorily. Several clinical investigations have also affirmed that computerized image guidance may be a viable strategy for facilitating transpedicular instrumentation in the lumbar spine.

In 2002, Laine et al.⁶⁸ studied the accuracy of image-guided lumbar instrumentation in their prospective, randomized clinical trial involving 100 subjects and nearly 500 pedicle screws. Postoperatively, the incidence of pedicle perforations was significantly lower in the IGT cohort compared with the control group whose screws had been implanted with a conventional technique (4.6% vs. 13.4%, respectively). Resnick⁷⁴ employed virtual fluoroscopy in 23 lumbar arthrodesis procedures and determined that in 96 of 97 cases the pedicle probe was in either an ideal or acceptable position, corresponding to a 99% positive-predictive value relative to traditional fluoroscopic visualization. In a retrospective clinicoradiological study, Costa et al.³⁵ reported an accuracy rate of 91.8% with preoperative CT-based navigation as against an accuracy rate of 95.2% with intraoperative CT acquisition. They also noted that intraoperative CT navigation and subsequent automerging of the anatomy allowed a significant reduction in operative time.

Disc Replacement Surgery

Long-term function of lumbar artificial discs depends on the optimal positioning in the sagittal and the frontal plane. McAfee et al.⁷⁵ in a clinical study of 100 patients, reported that 17% of the cases demonstrated a suboptimal (3–5 mm deviation) or bad (>5 mm deviation) position of the implants, necessitating eventual revision surgery. Smith et al. in 2006⁷⁶ performed a cadaver-based study of lumbar disc arthroplasty prostheses comparing IGS-guided prosthesis placement with biplanar C-arm. The image-guided technique appeared to increase the accuracy of prostheses placement in the coronal plane and improved their rotational alignment, while decreasing the degree of interprocedural variance and minimizing radiation exposure of the surgeon. This has also been confirmed by Rauschmann et al.^{77,78} in their cadaveric study comparing a conventional surgical technique with the use of a navigation. Marshman et al. in 2007 reported the first clinical study that demonstrated significantly improved accuracy of lumbar total disc arthroplasty placement via

postoperative CT using IGS compared with conventional fluoroscopy. They recommended the routine use of IGS during lumbar total disc arthroplasty.

Revision Surgeries

Revision spinal surgeries pose a great challenge to the surgeon because important anatomic landmarks may be obscured or even absent secondary to scar tissue formation, bony deformities, and other postoperative changes. In addition, the tactile feedback from native cortical and cancellous bone is lost. The presence of pre-existing hardware further poses a surgical challenge, often complicates the placement of subsequent implants, and alternative strategies may need to be considered in revision cases where there have been prior attempts at internal fixation.

Austin and coworkers⁷⁹ compared two methods of image guidance to an open technique for the insertion of pedicle screws in a cadaveric model of posterolateral thoracolumbar fusion. According to their analysis, the rates of pedicle perforation were 21.4% following laminoforaminotomy, 8.33% for fluoroscopic IGT, and 0% with CT-based navigation. Rampersaud and Lee reported⁸⁰ a 20% breach rate in 102 pedicle screws placed through mature fusion masses in revision spine surgery cases using 2D fluoroscopy-based image guidance.

Lim et al.⁸¹ performed a retrospective review of 78 patients with a prior lumbar fusion who underwent CT image guidance revision surgery. They reported a 4.1% cortical violation rate with no clinically apparent radicular pain or weakness. No pedicle screws required revision for malpositioning, and they concluded that the accuracy rate of stereotactic image-guided pedicle screw placement into a previously fused lumbar spine is 96%. A study by Nottmeier et al.³³ of 102 patients undergoing revision surgery under image guidance demonstrated a pedicle cortical breach rate of 7.8%. This was lower than that described by Rampersaud and Lee who used 2D image guidance, but higher than that reported by Lim et al. who used 3D image guidance.

Seichi and coworkers⁸² observed no neurological or vascular injuries in their series of revision cervical procedures (4 C1–C2 transarticular screws and 47 pedicle screws) performed using a frameless stereotactic IGT system, although the authors noted that the risk of sustaining a cortical breach was considerably higher when the reference frame arc could not be adequately fixed to the distorted vertebral body.

Application in Ventral Spine Surgery

Albert et al.⁸³ assessed the feasibility of using image-guided stereotaxy in performing anterior cervical corpectomy in a cadaveric-based study. The average distance from the lateral border of the trough to the medial border of the foramen transversarium in the standard trough group was 5.10 mm (range, 1.72–7.71 mm), and the average distance from the medial border of the foramen transversarium to the image-guided trough was 4.34 mm (range, 3.34–5.48 mm). Their study concluded that image guidance provided improved accuracy when compared with that of standard techniques, implying the clinical potential for image-guided corpectomy.

Klein et al.⁸⁴ assessed the feasibility of using an image-guided Kerrison punch when performing an anterior cervical foraminotomy. The authors were able to determine the distance of the Kerrison tip to the vertebral artery. Their study concluded that an image-guided Kerrison punch may be used successfully when performing cervical foraminotomies during an anterior cervical discectomy, thus eliminating the risk of potential vertebral artery injury.

Assaker et al.⁸⁵ were the first to describe a ventral image-guided procedure in the thoracic spine for the removal of a calcified thoracic disc herniation that was removed thoracoscopically.

Computed tomography based navigation system was used by Kim and coworkers⁸⁶ for treating thoracic disc herniations. The authors used the costotransversectomy technique and reported no neurologic or vascular complications as well as a complete decompression of the neural elements verified postoperatively with advanced imaging modalities.

Seichi et al.⁸⁷ reported the safety and efficacy of IGT-assisted anterior thoracic decompression in three patients with ossification of the posterior longitudinal ligament that were successfully treated through a thoracotomic approach. Ohmori et al.⁸⁸ reported the application of an image-guided approach to ventral decompression and corpectomy in three cases of thoracolumbar vertebral collapse.

The optimal fixation of the DRA to the spine remains an unsolved problem in ventral decompression procedures. The available options are fixation to the iliac crest, spinous process or transthoracically on a long stylus directly into a vertebral body. Problems with stable fixation exist with fixation to the iliac crest, limited visibility using navigation system if fixed to a spinous process or the problem of an obstructing object in the thoracic cavity if the Dynamic Reference Array (DRA) is fixed to a vertebral body.

Thoranaghatte et al.⁸⁹ have tried to address this problem by the hybrid navigation system that uses the endoscope as the tracking device. A fiducial marker is fixed to the spine and the position and orientation of the marker in space is determined by means of image analysis. This information is then correlated to the position of the endoscope, which is equipped with a DRA. This technique, which is still under evaluation, could obviate the need for a DRA.

Navigation in Minimally Invasive Surgeries

Percutaneous placement of pedicle screws is becoming routine in spine surgery with the advent of minimally invasive techniques. The reported benefits of minimally invasive techniques compared with open procedures include reductions in blood loss, length of hospital stay, infection rates, postoperative pain and time to return to work.⁹⁰

Minimally invasive pedicle screw fixation is associated with increased radiation exposure to the patient, surgeon and staff, along with higher risk of a misplaced screw. Studies have reported cortical breaches during percutaneous pedicle screw placement exceeding 15%,^{80,91,92} with neurological injury as high as 15%. Computerized navigation is ideally suited for MIS because these systems provide essential spatial and anatomic data without requiring any direct visualization of the spine itself. Three-dimensional fluoroscopy utility has been well established in various minimally invasive techniques such as TLIF (transforaminal lumbar interbody fusion), posterior fusion procedures, kyphoplasty and thoracic discectomy.

Initially, cadaveric studies were done using navigation for safety and accuracy. Sasso et al.⁹³ in 2005 evaluated the percutaneous placement of translaminar facet screws with the use of virtual fluoroscopy as an image guidance technique. No screws were placed in the spinal canal or in contact with the exiting nerve root and accurate screw placement was confirmed in all specimens.

Kim et al.⁶² in 2008 reported on a feasibility study of image-guided percutaneous pedicle screw fixation. They reported an average 12.4 milli-REM (mREM) of radiation exposure delivered to the surgeon during a unilateral MIS TLIF procedure without navigation (FLUORO group), whereas radiation exposure was undetectable in the navigation group. The total fluoroscopy time was also higher for the FLUORO group compared with the NAV group

(41.9 seconds vs. 28.7 seconds). No statistically significant differences were noted for operating time, estimated blood loss, or hospital stay. Li et al.⁹⁴ studied navigated percutaneous pedicle screw fixation in thoracolumbar fractures and reported a surgical time of 2.1 hours that was significantly shorter than that of the conventional pedicle screw fixation group (2.7 hours). Yang et al.⁹⁵ and Idler et al.⁹⁶ in two separate prospective studies concluded that the use of guidance reduces fluoroscopy and insertion times with increased accuracy compared with conventional fluoroscopic methods of percutaneous pedicle screw insertion. Jako et al.⁹² in a cadaveric demonstrated increased accuracy of percutaneous screw placement and reduced radiation exposure by means of a novel EM navigation system. The use of EM field navigation avoids the cumbersome line-of-sight issues of the optical-based systems, thus facilitating minimally invasive percutaneous procedures.

Villavicencio et al.⁹⁷ reported on the use of Iso-C 3D based navigation in 279 screws in 69 patients. Accuracy, operative time, and amount of fluoroscopic utilization time were assessed for TLIF and kyphoplasty cases. They concluded that use of intraoperative 3D fluoroscopy for image guidance in minimally invasive complex spinal instrumentation procedures is feasible and safe.

Balloon kyphoplasty is an accepted option after conservative treatment has failed to reduce the pain associated with osteoporotic vertebral fractures. The patient can be mobilized 24 hours after the procedure, and in most cases, pain is considerably attenuated or completely disappeared. Depending on the patient, the experience of the performing surgeon, and the level of the fractured vertebra, the average patient effective radiation dose during a balloon kyphoplasty procedure can be > 12 mSv. This radiation dose is three to four times higher than a full-body CT scan. In challenging cases of deteriorated anatomy and difficult radiomorphologic orientation, especially of the lower thoracic spine, image-guided kyphoplasty succeeds in finding the optimal pedicular approach to the vertebral body, helps to avoid collateral damage, and minimizes the overall risk of the procedure.⁹⁸ Izadpanah et al.⁹⁹ demonstrated significant reduced operating time and radiation dose in the navigated kyphoplasty group. The average radiation time was reduced significantly in the navigated group (99 seconds thoracic and 74 seconds lumbar). Radiation exposure to the patient was also significantly lower using image guidance (1,245 cGy cm² thoracic and 1,318 cGy cm² lumbar).

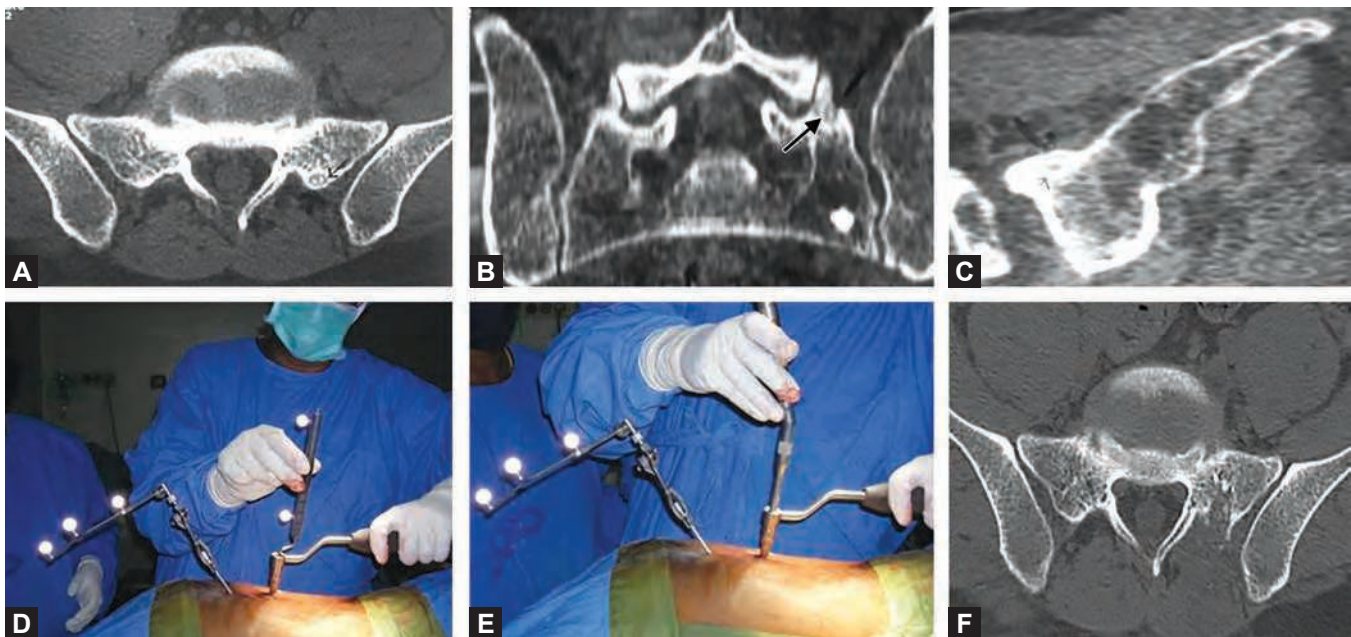

Johnson et al.⁹² evaluated quantitatively the application of frameless stereotactic image guidance in thoracoscopic discectomy procedures in 16 patients, who underwent image-guided thoracoscopic discectomy. Accuracy determined by registration (calculated) and navigation (intraoperative) was 1.7 and 1.2 mm, respectively. They concluded that image-guided thoracoscopic spinal surgery can provide 3D orientation to a 2D imaging procedure that ultimately improves accuracy, efficiency, and safety.

The evolving technology and the combination of intraoperative navigation and minimally invasive technology have allowed for the development of innovative operative treatment methods for addressing spinal pathology. MacMillan¹⁰⁰ has reported on an excellent 2-year results following computer-aided trans-sacral arthrodesis with percutaneous interbody fixation across the L5-S1 disc space. Webb et al.¹⁰¹ in a cadaveric study demonstrated the feasibility for performing minimally invasive direct lateral interbody fusion. However, additional studies will be needed to evaluate the efficacies of these approaches and validate many of the purported advantages.

Tumor Excision

Performing bone tumor resection using a navigation system can improve the accuracy of the surgical resection and help preserve function. Under navigated guidance, 3D anatomy of the tumor and the surrounding normal tissue can be visualized during surgery. Precise control of the resection margin is possible, enabling one to achieve the resection margin determined preoperatively. In selected patients, this technique can be helpful in increasing the accuracy of surgical resection and in reducing functional impairment. The key problem is that for successful navigation both soft tissues and bony structures need to be registered simultaneously. This prerequisite is not yet met in spinal tumor surgery. A possible solution is the development of navigated smart tools that interact with soft tissues only in the direct vicinity of the dissection without changing the spatial distribution of the surrounding tissue.²⁶

The efficacy of image guidance in pedicle screw placement in metastatic tumors has been proved by various authors.¹⁰² Arand et al. did a clinical study on the accuracy of CT-based decompression and insertion of pedicle screws in patients who have had tumor-related posterior surgery of the thoracic spine. In all eight patients accurate decompression of the spinal canal was seen. Eighty-six percent (19 of 22) of the navigated pedicle screws were positioned centrally in the bone. However, registration

Figs. 135.15A to F: Iso-C navigated percutaneous excision of sacral osteoid osteoma. Preoperative axial computed tomography (CT) images (A to C) show an osteoid osteoma (black arrow) of the sacrum. The osteoid osteoma is localized using the probe Nidus is marked by a black arrow mark. (D) and excised using a drill (E). Postoperative CT image (F) shows complete excision of the tumor.

errors can happen in the presence of significant bony destruction of the vertebrae necessitating safe fixation of the DRA away from the chosen vertebrae. Therefore, image-guided approaches should only be chosen in those cases where the DRB can be attached close to the vertebra being operated as distant fixation might result in significant registration errors.

Image-guided surgery helps in safe removal of certain benign bony tumors without destabilizing the spine. Rajasekaran et al.¹⁰³ reported on the efficacy of Iso-C 3D intraoperative spinal navigation in excising osteoid osteomas in four patients. A minimally invasive reflective array, tool navigator, and a registered burr were used for localization and deroofing of the lesion, followed by curettage and high-speed burring of the cavity. Complete removal of the nidus was confirmed intraoperatively by reacquisition of data (Figs. 135.15A to F). Conservation of bone allowed early mobilization and also removed the need for reconstruction. The authors concluded that intraoperative Iso-C 3D navigation is useful in accurately localizing and guiding complete excision of spinal osteoid osteomas through a minimally invasive approach without compromising spinal stability. The efficacy of this procedure was confirmed by van Royen et al.³ who confirmed the complete

removal of a radionuclide enhanced osteoid osteoma after 3D image-guided extirpation.

SUMMARY

Image-guided navigation surgery by linking image data to intraoperative spinal anatomy provides the surgeon with orientation to unseen anatomy, thus improving the safety and accuracy of spinal surgery.

Image guidance systems provide high accuracy of screw placement and safety for patients undergoing spinal stabilization in all areas of the spine. As the technology continues to advance, image guidance is becoming more user-friendly to the surgeon with little or no radiation exposure to the surgeon and the operating room staff. The clinical benefits of IGS for pedicle screw placement in terms of increasing accuracy and reduced radiation exposure have been clinically proven for spinal instrumentation. Navigation provides an effective method of applying instrumentation of spinal deformity and helps avoid potential complication due to implant malposition. The use of navigation in tumor surgery, minimally invasive spine surgery, and anterior spine surgery is evolving.

It is important that the surgeon develops a competency with this technology both intraoperatively with other

surgeons experienced with its use as well as in the laboratory. Image-guided surgery-based education in a skill laboratory setting helps to improve the locomotive capabilities necessary to perform safe and accurate surgery on the spine. However, it is important to remember that technology is not a substitute for a thorough knowledge of spinal anatomy and open methods of spinal instrumentation. Image-guided surgery serves as an additional source of information that can be used to make safe decisions intraoperatively.
